**ABSTRACT:** Tribological properties of ultrananocrystalline diamond nanowall (UNCD NW) films were investigated quantitatively in three different and controlled tribo-environmental conditions, proposing the passivation and graphitization mechanisms. However, these mechanisms are rather complicated and possibly can be understood in well-controlled tribological conditions. It was shown that the friction and wear of these films were high in high-

1  
2  
3 vacuum and room temperature (HV-RT) tribo-condition in which the passivation of carbon  
4  
5 dangling bonds was restricted and frictional shear-induced transformation of  $sp^3$  carbon into  
6  
7 amorphous carbon (a-C) and tetrahedral amorphous carbon (t-aC) was noticed. However, the  
8  
9 friction coefficient was reduced to the ultralow value in ambient atmospheric and room  
10  
11 temperature (AA-RT) tribo-condition. Here, both passivation of dangling bonds through  
12  
13 atmospheric water vapor and graphitization of the contact interfaces were energetically favorable  
14  
15 mechanisms. Furthermore, the conversion of diamond  $sp^3$  into hydrogenated-graphitized phase  
16  
17 was dominating mechanism for observed super-low friction coefficient and ultra-high wear  
18  
19 resistance of films in high-vacuum and high-temperature (HV-HT) tribo-condition. These  
20  
21 mechanisms were comprehensively investigated by micro-Raman and X-ray photoelectron  
22  
23 spectroscopy analyses of the sliding interfaces.

## 30 31 **1. INTRODUCTION**

32  
33 The crystalline diamond films are useful for several applications due to their unique  
34  
35 microstructure and chemical properties. Diamond is a wide band gap material<sup>1</sup> with high thermal  
36  
37 conductivity,<sup>2</sup> extreme hardness,<sup>3</sup> high elastic modulus<sup>3</sup> and unique friction and wear  
38  
39 performances.<sup>4-6</sup> All these outstanding properties of crystalline diamond are associated to the  
40  
41  $sp^3$ -hybridized chemical bonding of carbon atoms in cubic tetrahedral unit-cell parameter.<sup>7,8</sup>  
42  
43 Some of these properties of single crystal and micro/nanocrystalline diamond films were studied  
44  
45 reasonably well. Moreover, recently, field emission<sup>9,10</sup> and tribological properties<sup>11,12</sup> of  
46  
47 ultrananocrystalline diamond (UNCD) films were found to be superior as compared to the  
48  
49 micro/nanocrystalline counterpart. Boron enhanced growth of UNCD films showed improvement  
50  
51 in physicochemical and electrochemical properties.<sup>13,14</sup> This improvement is associated with  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 unique morphology and microstructure of ultranano diamond grains embedded with wider grain  
4 boundaries which occupy short-ranged crystalline graphite and amorphous carbon (a-C) phases.  
5  
6 Notably, improved tribological properties of crystalline diamond, including UNCD and  
7  
8 diamond-like carbon (DLC) films are generally explained by two existing mechanisms i.e.  
9  
10 passivation and graphitization of the sliding interfaces.<sup>5,6,12,15-21</sup> In the passivation mechanism,  
11  
12 the film surface being chemically inert is not much deformed which provides mechanical  
13  
14 stability. In contrast, the transformation of  $sp^3$  crystalline diamond into  $sp^2$  and a-C phases is  
15  
16 responsible for damage and deformation of the sliding interfaces.<sup>6,12,18</sup> Several aspects including  
17  
18 the internal chemical structure of films and tribo-test environment are governing factors for  
19  
20 determining passivation and/or graphitization mechanisms. However, these important aspects are  
21  
22 not yet quantitatively understood in the controlled atmosphere and high-temperature tribo-  
23  
24 condition in order to relate with friction and wear properties of the films.  
25  
26  
27  
28  
29

30  
31 Tribological properties of UNCD films show the strong dependence on humidity, gaseous  
32  
33 environment and vacuum tribo-condition.<sup>16,22</sup> At high humidity, the film showed ultralow  
34  
35 friction coefficient and high wear resistance and this was associated to the passivation of  
36  
37 dangling bonds of the sliding interfaces.<sup>16,22</sup> Moreover, Maria-Isabel *et al.* showed ultralow  
38  
39 friction of nanocrystalline (NCD) films in water vapor medium which is associated with the OH  
40  
41 and H passivation of the sliding surfaces.<sup>23</sup> Such improved properties of these films were  
42  
43 obtained even in dry environments where negligible rehybridization was observed and the low  
44  
45 friction behavior was supported by passivation mechanism.<sup>16,23</sup> In another study, low friction was  
46  
47 measured in low humidity (5%) condition and was understood due to graphitization of the sliding  
48  
49 interfaces.<sup>24</sup> Konicek *et al.* described that even low humidity is sufficient to passivate the  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

graphitized sliding interfaces.<sup>16</sup> Passivation mechanism of diamond surface was well described by adsorption-dissociation of water molecules.<sup>25</sup>

Interestingly, the friction coefficient was lower in more graphitized grain boundaries of UNCD films which was explained by the low shear resistance induced sliding mechanism between the graphitic sheets.<sup>11,12,26</sup> Even under mild tribological conditions, tribo-induced  $sp^3$  to  $sp^2$  hybridization was detected at the surface of wear track resulting in the formation of thin amorphous  $sp^2$ -rich carbon layer embedded with ultranano diamond grains.<sup>15</sup> Moreover, Bouchet *et al* described that the graphitization and passivation are together an effective mechanism for low friction and wear.<sup>15</sup> Passivation is essential even for  $sp^2$ -tribo-induced phase which is a by-product of  $sp^3$ -hybridized carbon, yielding low friction. The tribo-induced transformation from tetrahedral amorphous carbon (t-aC) and UNCD films to a-C and  $sp^2$  phase was experimentally observed by X-ray absorption near-edge fine structure technique and theoretically simulated by molecular dynamics (MD).<sup>27</sup> Zhang *et al.* observed such transformation in microcrystalline coarse grain diamond films in nitrogen atmosphere by Raman spectroscopy, resulting in low friction coefficient of 0.15.<sup>28</sup> Furthermore, tribo-induced phase transformation in single crystal diamond, yielding  $sp^2$ -hybridised amorphous layer was studied by MD simulations.<sup>29</sup> The  $sp^2$  carbon phase in diamond and DLC films is more active in high temperature tribo-condition. Therefore, the improvement in tribological properties of these films are challenging mainly due to transformation possibility of carbon phases at high temperature. At elevated temperatures and in ambient atmosphere condition, the DLC films undergo gradual transformation from a highly disordered or amorphous state to an increasingly ordered or graphitic state.<sup>30,31</sup> This is associated to thermodynamically unstable phase of DLC films. Therefore, friction and wear behaviors of DLC films are unstable and change with change in their chemical and structural properties at

1  
2  
3 higher temperatures. The hydrogenated DLC films may provide low friction up to 300°C for  
4 shorter sliding cycles, but during repeated sliding process, these films tend to wear faster.<sup>30</sup>  
5  
6 However, DLC films with hydrogen-free ta-C phase may last longer. Moreover, friction  
7  
8 coefficient of these films tend to increase with increasing test temperature due to thermal  
9  
10 desorption of water and other adsorbed species. Li *et al.* have shown that the friction coefficient  
11  
12 and wear rate of thermally annealed polycrystalline diamond films were reduced due to  
13  
14 formation of the carbonaceous transfer films.<sup>32</sup> Shabani *et al.* have investigated the high friction  
15  
16 value of multilayer micro/nanocrystalline diamond films at elevated temperature due to dry  
17  
18 contact condition.<sup>33</sup> However, ultralow friction coefficient in polycrystalline diamond films was  
19  
20 measured at moderate temperature in oxygen atmosphere.<sup>34</sup> This was ascribed to the chemically  
21  
22 stable adsorbed oxygen moiety formation on the film surface that saturates carbon dangling  
23  
24 bonds of diamond films.<sup>35,36</sup> Moreover, shear-induced graphitization of the sliding interfaces  
25  
26 may possibly explain the low friction in polycrystalline diamond films.<sup>35,37</sup> In high vacuum  
27  
28 conditions, graphitization and amorphization of diamond films are substantial which has an  
29  
30 adverse effect on friction and wear response. This can be explained by the lack of external  
31  
32 passivation when chemical adsorbate is absent to passivate the unsaturated bonds at sliding  
33  
34 interfaces.<sup>38,39</sup> However, hydrogenated UNCD films show low/ultralow friction value in high  
35  
36 vacuum condition due to passivation mechanism.<sup>26,40</sup> This was performed by hydrogen  
37  
38 atoms/molecules intrinsically present in the films. Moreover, at moderate temperature, surface  
39  
40 graphitization of diamond films was favorable in reducing the friction in air and vacuum  
41  
42 conditions.<sup>41,42</sup> Furthermore, ultra-low friction coefficient with high wear resistance was  
43  
44 measured at 200°C in UNCD films and this was explained by the formation of chemically  
45  
46 passivated sliding interfaces. However, at higher temperature, tribological performance of these  
47  
48

1  
2  
3 films were significantly degraded and failure happened mainly due to oxidation and  
4 amorphization/polymerization of the sliding interfaces.<sup>43</sup> Therefore, passivation of dangling  
5 bonds and conversion of  $sp^3$  into  $sp^2$  and a-C mainly depend on the temperature and  
6 environmental conditions. However, it is quite difficult to understand the suitable mechanism of  
7 friction and wear behavior in high-vacuum and high-temperature tribo-conditions without  
8 substantial characterization of tribofilm which was produced at sliding interfaces. Sustainable  
9 performance of materials in above mentioned tribo-conditions is useful for high temperature and  
10 space applications. However, tuning the tribo-sustainable properties of thin films via tailoring  
11 morphology, chemical composition and microstructure is a challenging task.

23  
24 Here, we report the deposition of tribologically novel and sustainable UNCD nanowall  
25 (NW) thin films using microwave chemical vapor deposition system employing the unique  
26 plasma conditions. To elucidate the comprehensive tribological properties, the test of UNCD  
27 NW films were conducted in the controlled tribo-environmental conditions such as ambient  
28 atmosphere and room temperature (AA-RT), high-vacuum and room temperature (HV-RT) and  
29 high-vacuum high-temperature (HV-HT). In order to explain the distinct underlying tribo-  
30 mechanisms, these tribo-atmospheres were used to manipulate the chemical nature of contact  
31 interfaces. The change in the chemical structure of tribo-interfaces was characterized by Raman  
32 spectroscopy and X-ray photoelectron spectroscopy with micrometer spatial resolution.

Chemical modification of carbonaceous tribofilm at contact interfaces in three different tribo-  
conditions was quantitatively explained by shear induced amorphization/graphitization and  
passivation mechanisms. Moreover, friction and wear behavior was explained based on the  
chemical structure of tribofilms at the sliding interfaces.

## 2. EXPERIMENTAL SECTION

1  
2  
3 **2.1. Film Deposition.** UNCD nanowalls films were deposited on (100) oriented silicon substrate  
4 using microwave plasma enhanced chemical vapor deposition (MWPECVD; SEKI Technotron  
5 AX5400S, Japan) system. The base pressure inside the chamber was  $10^{-4}$  Torr. Prior to diamond  
6 growth, the silicon substrate was seeded by spin-coating in the diamond slurry.<sup>44</sup> The nanowalls  
7 have been fabricated using the following process conditions: gas mixtures of CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub>  
8 with a total flow rate of 328 sccm, microwave power of 1300 W, the process pressure of 50 Torr,  
9 and microwave radiation frequency of 2.45 GHz. During the deposition process, the substrate  
10 holder was heated up to 700°C by an induction heater, which was controlled by a thermocouple.  
11 The deposition parameters of these films differ from earlier UNCD nanowire films deposited in  
12 CH<sub>4</sub>/N<sub>2</sub> plasma condition without the addition of H<sub>2</sub>.<sup>11,12</sup>

13  
14  
15 **2.2. Characterization Techniques.** Morphology of these films was characterized by field  
16 emission scanning electron microscopy (FESEM, Zeiss Supra 55). High-resolution  
17 microstructure and crystallographic investigation of UNCD nanowall films were examined by  
18 transmission electron microscopy (TEM; JOEL 2100). Bonding structure of films surface, wear  
19 tracks and ball scars were studied by micro-Raman spectrometer (Andor SR-500i-C-R,  
20 wavelength 532 nm). Chemical bonding of films surface, wear tracks and ball scars were  
21 characterized by energy dispersive X-ray spectroscopy (EDS). Wide range survey and high-  
22 resolution X-ray photoelectron spectroscopy (XPS) of films and mechanochemically modified  
23 contact interfaces were recorded by Sigma probe-Thermo VG Scientific equipped with  
24 hemispherical analyzer and micro-focused monochromator X-ray source with spatial resolution  
25 of 50 μm. The XPS analysis was carried out using Al Kα radiation (E=1486.6 eV) with an  
26 energy resolution of 0.47 eV in ultra-high vacuum at  $10^{-10}$  Torr.

1  
2  
3 **2.3. Tribology Tests Condition.** Friction and wear behaviors of UNCD NW films were studied  
4  
5 by ball-on-disc high-vacuum high-temperature tribometer (HV-HT Anton Paar, Switzerland)  
6  
7 operating in a circular motion mode. For friction measurements; normal load, sliding speed and  
8  
9 diameter of sliding contact were 0.5 N, 50 rpm and 5 mm, respectively. Alumina ( $\text{Al}_2\text{O}_3$ ) ball  
10  
11 with 6 mm diameter was used as a sliding counterbody. The hardness of  $\text{Al}_2\text{O}_3$  ball is 12 GPa  
12  
13 and average roughness of 45 nm. The above values were standardized and provided by the  
14  
15 supplier (HV-HT Anton Paar, Switzerland). The tribo-tests were conducted in three different  
16  
17 atmospheres: (a) AA-RT with ambient atmosphere and room temperature (b) HV-RT with  
18  
19 vacuum level  $\sim 5 \times 10^{-6}$  mbar and room temperature (c) HV-HT with vacuum level  $\sim 5 \times 10^{-6}$  mbar  
20  
21 and film temperature  $\sim 623$  K. Two dimensional (2D) wear profile was measured by Dektak 6M-  
22  
23 stylus profiler for the wear analysis.

### 30 **3. RESULTS AND DISCUSSION**

31  
32 **3.1. Morphology and Microstructure.** SEM micrographs shown in [Figure 1a](#) indicated that  
33  
34 UNCD NW films shows predominantly nanowall-like feature with the size of 200 to 300 nm in  
35  
36 length. These features are homogeneously distributed all over the film surface. [Figure 1b](#) shows  
37  
38 the bright field TEM (BF-TEM) micrograph of UNCD NWs, revealing the unique granular  
39  
40 structure of these films. The UNCD NW films consist of needle-like clusters of hundreds of  
41  
42 nanometers in length. The selected area diffraction (SAED) pattern showed (111), (220), and  
43  
44 (311) rings of diamond plane and a central diffuse ring of  $\text{sp}^2$ -bonded carbon (nanographite or a-  
45  
46 C phase) or *trans*-polyacetylene (TPA) located in the grain boundaries. The presence of  
47  
48 diffraction rings implies that the needle-like clusters are predominantly diamond and the  
49  
50 diamond grains are randomly oriented, whereas the central diffuse ring is presumably  
51  
52

3 *NWs. The insets FT<sub>1</sub> and FT<sub>2</sub> of figure 1(c) show the Fourier-transformed (FT) diffractogram*  
4 *images corresponding to regions 1 and 2, respectively.*  
5  
6  
7

8 The needle-like clusters contain diamond about 5 nm in width and hundreds of nanometers in  
9 length as core and sp<sup>2</sup>-bonded carbon (nanographite or amorphous carbon) as shell. The FT<sub>1</sub> and  
10 FT<sub>2</sub> Fourier-transformed diffractogram further confirmed that the core and shell consists of  
11 diamond and sp<sup>2</sup>- bonded carbon, respectively. There exists an extra ring with smaller size than  
12 (111) ring (indicated by the arrow in inset of Figure 1b), which corresponds to *n*-diamond (*n*-D),  
13 a metastable form of diamond with FCC structure and cell parameter of 0.356 nm.<sup>45,46</sup> It is worth  
14 mentioning that the morphology and microstructure of the present films differ significantly from  
15 our published results and this fact is related to altered plasma condition during deposition  
16 process.<sup>11,12</sup> Here, UNCD NW exists in nanowall feature embedded with a-C structure. However,  
17 in earlier work, nanowire like feature was formed.<sup>11,12</sup>

31 **3.2. Bonding Structure of Bulk and Surface of Films.** The bonding structure of bulk and  
32 surface of films were comprehensively investigated by Raman spectroscopy and XPS analyses  
33 and the results are shown in Figure 2. Raman spectra showed four deconvoluted peaks  
34 designated by  $\nu_1$  (1168 cm<sup>-1</sup>),  $\nu_3$  (1510 cm<sup>-1</sup>), D (1329 cm<sup>-1</sup>) and G (1582 cm<sup>-1</sup>) bands which are  
35 the nondiamond phases existing in the grain boundaries<sup>47</sup> (Figure 2a). The  $\nu_1$  and  $\nu_3$  correspond  
36 to TPA phases<sup>48,49</sup> and the other two D and G bands with I(D)/I(G) ratio of 1.65 shows the  
37 signature of a-C and graphite phases.<sup>50</sup> Fundamental phonon band of diamond in UNCD is not  
38 observable mainly for two reasons: (a) broadening effect due to phonon confinement in ultranano  
39 grains and (b) quenching of diamond band due to appearance of broad nondiamond D band at  
40 similar Raman shift. Such a Raman characteristic is a signature of UNCD films.<sup>11,51</sup> More  
41 detailed surface bonding characteristics was investigated by XPS (Figure 2b-d). Survey spectra

59  
60

in Figure 2b showed photoelectron emission of carbon (C1s) and oxygen (O1s) at 285.5 and 531.1 eV,<sup>52</sup> respectively, of UNCD NW film and C/O ratio is 2.92. A small fraction of oxygen at films surface is associated to the contamination due to exposure in ambient environment. Moreover, Auger photoelectron shift of these elements as OKLL and CKLL are also observed. Another weak chemical shift of N1s photoelectron was observed at 399.32 eV which signifies the impurities associated to nitrogen gas in plasma medium used for the deposition of UNCD NW films. X-ray photoelectron emission of Si2p and Si2s lines, related to the silicon substrate, were also observed in trace level as impurities.

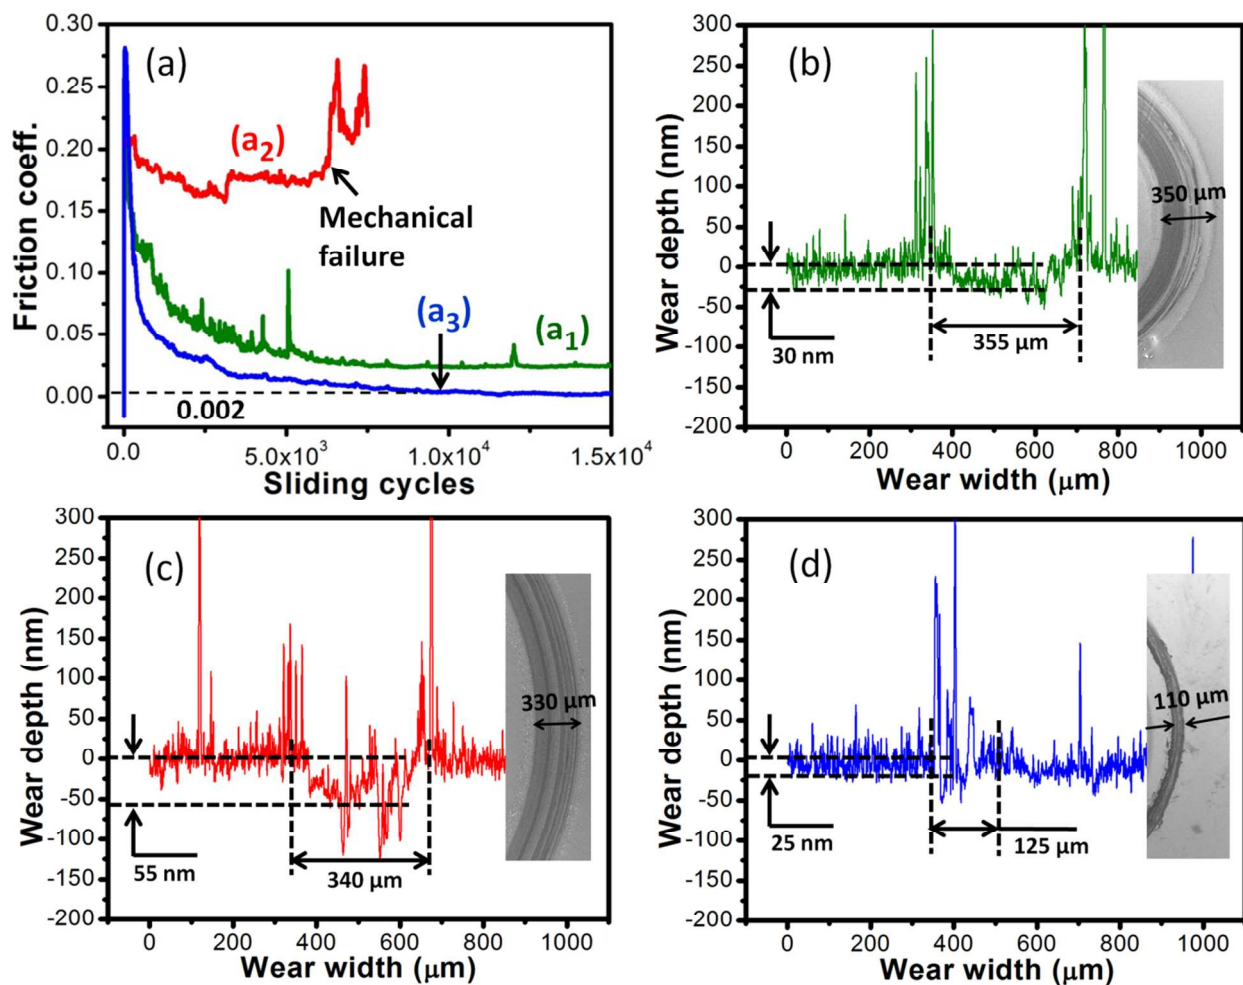

**Figure 2.** (a) Raman spectra and (b-d) XPS spectra of UNCD NW film surface: (b) survey spectra and high-resolution XPS: (c) C1s and (d) O1s X-ray photoelectron emission lines.

1  
2  
3 High-resolution (HR) XPS of photoelectron emission bands of C1s and O1s are plotted in  
4 [Figure 2c](#) and [2d](#), respectively. A broad C1s photoelectron emission spectrum is deconvoluted  
5 into four peaks at the binding energies of 284.46, 285.3, 286.6 and 288.7 eV. The background  
6 was subtracted following the Shirley method.<sup>53</sup> The first two peaks are designated as  $sp^2$  and  $sp^3$   
7 hybridized carbon and third and fourth peaks correspond to oxygen functional groups such as the  
8 carboxylic (C-O/C-OH) and carbonyl (C=O) groups, respectively.<sup>22,54,55</sup> The ratio of  $sp^3/sp^2$   
9 phase is 1.48 and energy width of photoelectron emission for  $sp^2$  and  $sp^3$  peaks are equivalent to  
10 1.55 and 1.54 eV, respectively. These films showed the large fraction of  $sp^2$  carbon phase as  
11 compared to earlier reported work<sup>11,12</sup> and therefore, chemical properties of these UNCD NW  
12 films are distinctly different and novel for tribological applications. Moreover, deconvolution of  
13 broad O1s peak results in three photoelectron emission lines centered at binding energies of  
14 530.65, 531.7 and 532.9 eV that correspond to the C=O, C-O and C-OH functional groups,  
15 respectively.<sup>22,56</sup> These groups are attainable due to the surface contamination and adsorption of  
16 atmospheric moisture and water vapor molecules.

17  
18  
19 **3.3. Friction and Wear Characteristics.** Friction and wear behavior of UNCD NW films  
20 distinctly differ depending upon their tribo-test environments ([Figure 3](#)). Two separate  
21 measurements for each tribo-condition were carried out and in each condition, the measurement  
22 was found to be reproducible. The saturated value of friction coefficient in AA-RT was  $\sim 0.023$   
23 (curve  $a_1$ ) which significantly increased to  $\sim 0.17$  in HV-RT tribo-condition (curve  $a_2$ ) and in  
24 addition, early film failure was also noticed. However, the friction value was decreased to  $\sim 0.002$   
25 in HV-HT tribo-condition (curve  $a_3$ ). Raw data of friction curves in all three different  
26 atmospheres are presented in Supplementary Information ([Figure S1](#)). Wear dimension is found

57  
58  
59  
60

to be directly proportional to the friction value and it is lowest in HV-HT as compared to other two conditions (Figure 3d).

**Figure 3.** (a) Friction coefficient vs sliding cycles of UNCD NW film: (a<sub>1</sub>) AA-RT (a<sub>2</sub>) HV-RT and (a<sub>3</sub>) HV-HT tribo-condition, and 2D wear track profile in (b) AA-RT (c) HV-RT and (d) HV-HT tribo-condition. SEM images of the corresponding wear tracks are embedded for each condition; tribology parameters: load: 0.5 N, speed: 50 rpm, ball: Al<sub>2</sub>O<sub>3</sub> (dia. 6 mm).

Four wear profile measurements were performed for each wear track at random locations and the data were quite repeatable. Wear dimension evidence is well supported by the low-resolution

SEM images embedded in [Figure 3b-d](#). Moreover, high-resolution SEM images of wear track formed in AA-RT condition showed that the nanostructure feature of UNCD NW films was sustained without much deformation ([Figure S2](#)). However, plastically deformed nanostructured morphology of UNCD NW in the wear track was observed in HV-RT tribo-condition ([Figure S3](#)). In this case, the wear dimension and extent of deformation of the ball is much higher compared to AA-RT condition. Contrasting SEM image of the wear track formed in HV-HT was observed with transformation of the UNCD NW morphology into layered deformed patches ([Figure S4](#)). Furthermore, in this case, deformation of ball and wear track dimensions much less. It is worth mentioning that in HV-HT condition, films were highly wear resistant with wear loss of 0.0016 nm/cycles. However, wear loss of films in AA-RT and HV-RT tribo-condition was 0.002 nm/cycles and 0.006 nm/cycles, respectively. It shows that the wear resistance of the films in HV-HT was improved up to 17% and 55% as compared to AA-RT and HV-RT tribo-condition, respectively. Tribological properties of UNCD nanowire films were studied earlier by our group in ambient atmosphere and room temperature condition.<sup>11,12</sup> However, in this present study, the value of friction coefficient of UNCD NW films is lower than UNCD nanowire films. Moreover, friction value of UNCD NW films is almost vanishing to the value of 0.002 with negligible wear loss in HV-HT condition. This value is much less compared to earlier reported work.<sup>11,12,16,22-24</sup> To the best of our knowledge, this is a first tribological measurement on UNCD NW films conducted in three different controlled environments for comparative studies. Moreover, in-depth chemical characterizations of sliding interfaces were performed comprehensively to understand the governing friction and wear mechanisms. These are discussed in the following sections.

#### 4. CHEMICAL COMPOSITION AND PHASE ANALYSIS OF SLIDING INTERFACES

**4.1. EDS Analysis of Sliding Interfaces.** EDS analysis was carried out for qualitative elemental analysis of wear product and chemical composition of tribo-contact interfaces in three different tribological conditions. The results are presented in [Figure S5-7](#). Wear track analysis showed the localized patch formation of O and Al entities as shown in the micrograph in AA-RT tribo-condition ([Figure S5a](#)). A typical patch designated as (a<sub>2</sub>) and corresponding spectra (b<sub>2</sub>) is shown in [Figure S5b](#). These elements are wear product of Al<sub>2</sub>O<sub>3</sub> ball which is formed due to deformation in AA-RT tribo-condition. However, whole area mapping denoted by (a<sub>1</sub>) does not show the significant quantity of O and Al in spectra (b<sub>1</sub>), indirectly indicating the localized formation of Al<sub>2</sub>O<sub>3</sub> as a wear product. Here, the contribution of atmospheric oxygen along with oxygen from Al<sub>2</sub>O<sub>3</sub> is worth to mention. In the similar tribo-condition, ball contact showed the signature of C and this is a product of transferlayer from UNCD film onto Al<sub>2</sub>O<sub>3</sub> ball sliding contact. These are indicated in EDS mapping spots of (c<sub>1</sub>-c<sub>3</sub>) in [Figure S5c](#) and corresponding spectra in (d<sub>1</sub>-d<sub>3</sub>) in [Figure S5d](#). Atomic fraction of deformed wear product of Al<sub>2</sub>O<sub>3</sub> ball was negligible in the wear track of HV-RT tribo-condition ([Figure S6a](#)). Therefore, the EDS spectra of the whole region (a) showed the negligible atomic fraction of Al and O and in this particular environment, the oxidation was also restricted due to the high vacuum condition ([Figure S6b](#)). However, bulk quantities of these elements present at the ball scar is an indication of Al<sub>2</sub>O<sub>3</sub> ball ([Figure S6d](#)). More importantly, the X-ray signal of C is strong at the ball scar and this indicates the formation of transferfilm. The location at ball scar for EDS analysis is indicated in [Figure S6c](#). The negligible fraction of Al and O was observed at the wear track of UNCD films in HV-HT tribology condition. The EDS mapping spots are shown as (a<sub>1</sub>-a<sub>2</sub>) in [Figure S7a](#) and corresponding spectra are presented in (b<sub>1</sub>-b<sub>2</sub>) of [Figure S7b](#), respectively. More importantly, in

1  
2  
3 this case, the atomic fraction of C is high at the ball scar due to transferfilm formation. This is  
4 shown in spots (c<sub>1</sub>-c<sub>2</sub>) in [Figure S7c](#), and corresponding spectra in (d<sub>1</sub>-d<sub>2</sub>) in [Figure S7d](#).  
5  
6 Qualitatively, it is concluded that carbon transferfilm is present on ball scar in all the three tribo-  
7  
8 conditions. Atomic percentage of carbon is large in HV-RT and HV-HT tribology conditions  
9  
10 compared to AA-RT. However, EDS technique being bulk sensitive is not sufficient to  
11  
12 investigate the chemical phase composition of carbon at sliding interfaces. Therefore, the  
13  
14 combination of spatially resolved Raman and XPS techniques were used for in-depth chemical  
15  
16 phase composition analysis of sliding interfaces in three different tribo-conditions. These are  
17  
18 discussed in the following sections.

23

24 **4.2. Raman Spectroscopy of Sliding Interfaces.** Wide frequency range of raw Raman spectra  
25  
26 and the corresponding deconvoluted spectra of UNCD NW films in the specific range for AA-  
27  
28 RT tribo-condition are shown in [Figure 4a](#) and [4b](#), respectively. For comparison purpose, all the  
29  
30 parameters of Raman spectrometer were kept similar. The Raman spectrum of the film surface is  
31  
32 also presented for reference purpose.

**Figure 4.** (a and b): Raw data of Raman spectra of film surface ( $a_1$ ) and inside the wear track ( $a_2$ )&( $a_3$ ) and corresponding deconvoluted spectra ( $b_1$ - $b_3$ ), respectively; (c and d): raw data of Raman spectra at ball scars ( $c_1$ - $c_3$ ) and deconvoluted spectra ( $d_1$ - $d_3$ ), respectively; tribology parameters: load: 0.5 N, speed: 50 rpm, ball:  $Al_2O_3$  (dia. 6 mm), condition: ambient and room temperature (AA-RT).

Chemical structure of the UNCD NW wear track is stable and does not show the large difference in I(D)/I(G) value (Figure 4b). This ratio is an important parameter for the determination of the chemical structure of carbon phase.<sup>50</sup> However, the marginal increase in this ratio locally inside the wear track signifies slight enhancement in a-C/sp<sup>2</sup> phase. This change clearly showed the increase in intensity counts in ( $a_3$ ) of Figure 4a. Moreover, D and G peak position inside the wear track is quite similar to the film surface. There is not much change in TPA phase inside the wear track and this fact directly points towards the stable UNCD structure in AA-RT tribo-condition.

1  
2  
3 Chemical stability of this structure can be explained by passivation of sliding interfaces through  
4 ambient atmospheric chemical species. Similar Raman shift at the ball scar clearly indicates the  
5 formation of carbonaceous film (Figure 4c). However, peak shape, intensity and peak position of  
6 tribofilm locally differs at the ball scar which is an indication of heterogeneous carbonaceous  
7 transferfilm formation. This is shown in deconvoluted spectra ( $d_1$ - $d_3$ ) of Figure 4d. Moreover,  
8  $I(D)/I(G)$  value is less and the blue shift in D and G bands is noticed at the ball scar compared to  
9 wear track. This is a direct indication of shear induced a-C to graphitization in the ambient  
10 atmospheric condition.<sup>57</sup> This may also be confirmed by the weakness of TPA phase due to the  
11 chemical modification of UNCD structure. Further, the altered shape of the Raman bands with  
12 the decrease in  $I(D)/I(G)$  value in the range of 0.9 to 1 was observed at most of the places of ball  
13 scar. However, locally this value was reached to 1.4 which showed stable tribofilm formation of  
14 chemically modified UNCD NW phase at the ball scar.

29  
30  
31 UNCD structure of wear track in the HV-RT tribo-condition is also stable and the Raman  
32 bands are more or less comparable to virgin UNCD film surface. The results of Raman spectra of  
33 wear track in HV-RT tribo-condition are shown in Figure 5a-b.

**Figure 5.** (a and b): Raw data of Raman spectra of film surface (a<sub>1</sub>) and inside the wear track (a<sub>2</sub>)&(a<sub>3</sub>) and corresponding deconvoluted spectra (b<sub>1</sub>-b<sub>3</sub>), respectively; (c and d): raw data of Raman spectra at ball scars (c<sub>1</sub>-c<sub>3</sub>) and deconvoluted spectra (d<sub>1</sub>-d<sub>3</sub>), respectively; tribology parameters: load: 0.5 N, speed: 50 rpm, ball: Al<sub>2</sub>O<sub>3</sub> (dia. 6 mm), condition: high-vacuum ( $5 \times 10^{-6}$  mbar) and room temperature (HV-RT).

In this HV-RT condition, Raman peak parameters such as peak shape, peak position, I(D)/I(G) value and TPA phase of UNCD in wear track are quite similar to the wear track formed in AA-RT tribo-condition. However, the chemical structure of carbonaceous tribofilm formed at the ball scar is completely transformed into a-C and t-aC structure.<sup>58</sup> This is noticed by the significant change of peak shape, peak position and modified value of I(D)/I(G) ratio as shown in (d<sub>1</sub>-d<sub>3</sub>) of Figure 5d. In this condition, the blue shift in D and red shift in G bands was observed as

1  
2  
3 compared to carbon structure of wear track. Here, TPA phase is completely disappeared and this  
4  
5 could be a strong indication for the conversion of UNCD into a-C and t-aC structure. This could  
6  
7 be possible due to the high frictional energy which acts as activation energy for such  
8  
9 transformation. Therefore, in case of HV-RT, the ball scar is fully covered by bulk tribofilm of a-  
10  
11 C and t-aC phases. Thus, in this particular condition, sliding occurred between UNCD NW film  
12  
13 and a-C/t-aC structure on ball side.  
14  
15

16  
17 Distinct changes in Raman spectra of the sliding interfaces in HV-HT tribology condition  
18  
19 were noticed as shown in Figure 6a-d. Here,  $I(D)/I(G)$  value of film surface is 1.52 as shown in  
20  
21 (a<sub>1</sub>) of Figure 6a. This value is less compared to the ambient UNCD film as shown earlier in  
22  
23 Figure 2a and (a<sub>1</sub>) of Figure 4a.

5 *mbar) and high-temperature (623 K) (HV-HT).*  
6  
7  
8  
9

10 Moreover, at high vacuum high-temperature condition, the D and G bands are blue shifted  
11 indicating temperature induced annealing which tends to reorient the carbon structure into more  
12 ordered sp<sup>2</sup> phase. However, I(D)/I(G) ratio is significantly decreased in the wear track as  
13 compared to the film surface as shown in (b<sub>2</sub>-b<sub>3</sub>), [Figure 6b](#). For better quantitative analysis,  
14 Raman spectra are obtained at several locations of wear track in all three different tribology  
15 conditions ([Figure S8](#)). The Raman analysis showed the shift of D and G bands to higher  
16 wavenumber and decrease in I(D)/I(G) ratio in HV-HT condition. This behavior describes bulk  
17 graphitization of the contact surface<sup>57</sup> and it is contrasting to the wear track formed in AA-RT  
18 and HV-RT tribo-condition as mentioned above. This indicates that the contact pressure at high  
19 temperature in high vacuum tribo-condition is a deterministic factor to reorient the disordered sp<sup>2</sup>  
20 into more ordered sp<sup>2</sup> phase. Moreover, conversion of sp<sup>3</sup> to sp<sup>2</sup> phase is also possible and it  
21 depends on the activation energy which is gained by the temperature and contact pressure. Most  
22 portion of the ball scar is covered by graphitized transfer film where I(D)/I(G) ratio is 0.98 as  
23 shown in (d<sub>1</sub>) of [Figure 6d](#). However, graphitized tribofilm is highly distorted at few localized  
24 positions of the ball scar (d<sub>2</sub>-d<sub>3</sub>) in [Figure 6d](#). This is confirmed by the distinct shape of Raman  
25 bands with the increase in I(D)/I(G) value. Here, raw data of (c<sub>2</sub>-c<sub>3</sub>) in [Figure 6c](#) showed very  
26 weak intensity of D and G bands which indicates the thin layer of distorted carbon structure. It is  
27 worth mentioning that Raman spectroscopy is a bulk sensitive technique and therefore, formation  
28 of such above mentioned phases is a bulk phenomenon. This was earlier reported by Bouchet *et*  
29 *al.* which showed formation of 40 nm thick sp<sup>2</sup> rich carbon layer at the top of coating.<sup>15</sup> The sp<sup>2</sup>

5 for amorphous ta-C films with even larger thickness of 50 nm.<sup>59</sup>  
6

7  
8 **3. X-ray Photoelectron Spectroscopy of Ball Scar.** XPS was used for more insightful surface  
9  
10 chemical analysis of tribofilm deposited on the ball contact region during the sliding process.  
11  
12 This is an essential tool for understanding the friction behavior in three different tribo-conditions.  
13  
14 The spatial resolution of XPS was 50  $\mu\text{m}$  and therefore, it was possible to focus the X-ray at  
15  
16 specific locations inside the wear scar region of the ball surface. For this purpose, mainly  
17  
18 deformed and less deformed regions were selected at each ball scar for quantitative chemical  
19  
20 analysis. It is worth mentioning that these selected regions are representative of full scar. The  
21  
22 common spots for Raman and XPS were located for comparative chemical analysis. Survey XPS  
23  
24 showed well resolved C1s and O1s photoelectron shift obtained from the ball scar region in three  
25  
26 different tribo-conditions such as AA-RT, HV-RT and HV-HT. These spectra are shown in  
27  
28 [Figure 7-9b](#) and the corresponding physical locations of spectra are indicated in optical images in  
29  
30 [Figure 7-9a](#), respectively. These results show the carbonaceous tribofilm formation at the  $\text{Al}_2\text{O}_3$   
31  
32 ball with adsorbed oxygen content. Survey spectra showed that in AA-RT tribo-condition, C/O  
33  
34 ratio is less at the deformed region (0.51) as compared to the plain/less deformed region (0.68)  
35  
36 and intensity of the alumina peaks (Al2p and Al2s) is strong in deformed region ([Figure 7b](#)).  
37  
38 These regions are located as (a<sub>1</sub>) and (a<sub>2</sub>) in [Figure 7a](#).

55  
56  
57  
58  
59  
60

**Figure 7.** (a) Optical image of ball scar in AA-RT tribo-condition: (a<sub>1</sub>) deformed and (a<sub>2</sub>) less deformed region and corresponding survey XPS spectra of (b<sub>1</sub>) and (b<sub>2</sub>), respectively; HR-XPS of C1s and O1s of (c and d) deformed and (e and f) less deformed region, respectively.

This indicates the excess exposure of alumina at the deformed region. Here, C/O ratio is much lower as compared to the virgin film surface due to tribo-induced adsorption of oxygen (Figure 2b). The effective adsorption of oxygen is associated to the high energy of deformed Al<sub>2</sub>O<sub>3</sub> ball surface which further react with the water vapor, forming adsorbed oxygen contamination. HR-XPS of C1s photoelectron shift obtained from both the locations i.e. deformed and less deformed

1  
2  
3 regions showed well-resolved deconvoluted  $sp^3$  and  $sp^2$  peaks with the contribution of oxygen  
4 functional groups. These are represented in Figure 7c and 7e, respectively. The  $sp^3/sp^2$  ratio in  
5  
6 deformed and less deformed region is 0.65 and 0.6, respectively. These values are much lower as  
7  
8 compared to virgin film surface (Figure 2c) and it is an indicative of tribo-chemical conversion  
9  
10 of  $sp^3$  to  $sp^2$  phase. In these regions, HR-XPS of O1s photoelectron shift showed well-resolved  
11  
12 oxygen functional groups<sup>52</sup> (Figure 7d and 7f) and spectral characteristics are similar to virgin  
13  
14 film surface (Figure 2d). This indicates that the chemical environment of functional groups does  
15  
16 not depend much on deformation of  $Al_2O_3$  ball surface. In contrast, adsorption of oxygen  
17  
18 quantity directly depends on the deformation which is related to the change in surface energy.  
19  
20  
21  
22  
23

24 Survey spectra showed C/O ratio of 0.68 and 0.48 at two different locations of the scar  
25  
26 formed in HV-RT tribo-condition (Figure 8b). These regions are located in (a<sub>1</sub>) and (a<sub>2</sub>) of Figure  
27  
28 8a, respectively.

56  
57  
58  
59  
60

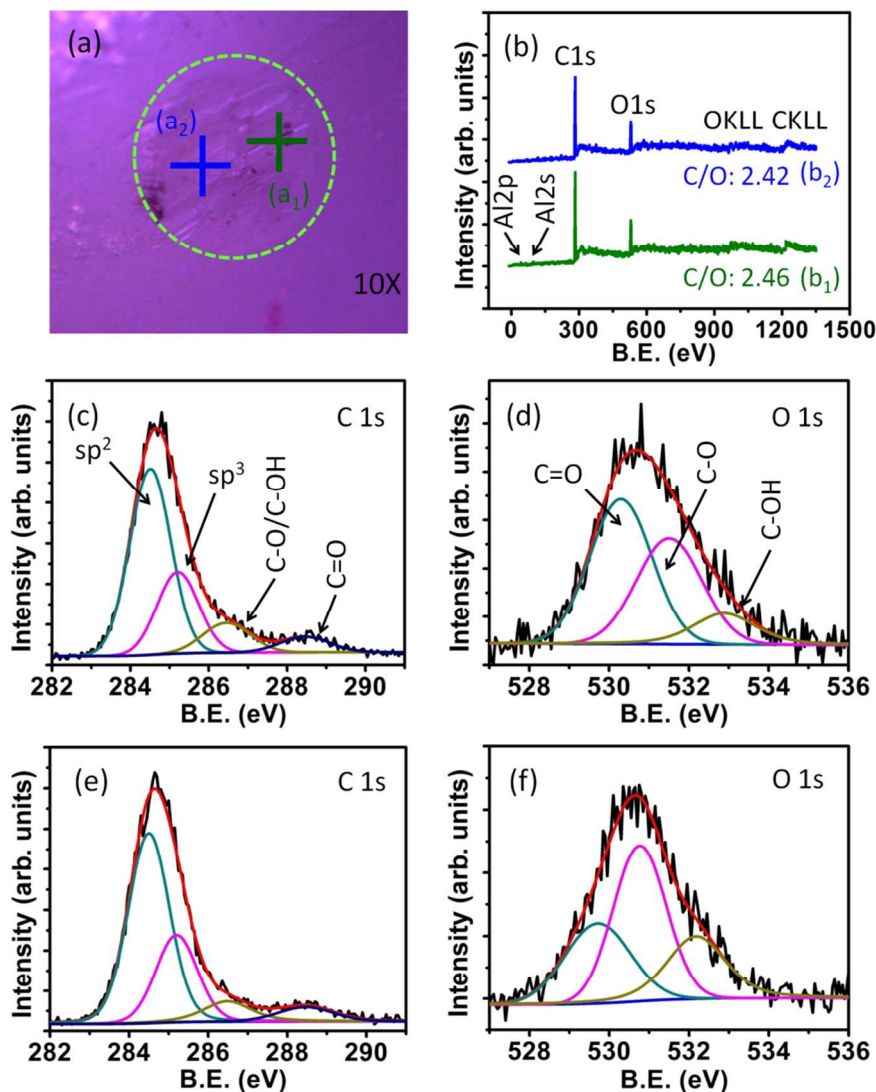

**Figure 8.** (a) Optical image of ball scar in HV-RT tribo-condition: (a<sub>1</sub>) deformed and (a<sub>2</sub>) less deformed region and corresponding survey XPS spectra of (b<sub>1</sub>) and (b<sub>2</sub>), respectively; HR-XPS of C1s and O1s of (c and d) deformed and (e and f) less deformed region, respectively.

In this condition, contribution of oxygen contamination is mainly due to exposure of film sample in ambient atmosphere after conducting the tribo-tests. Further, the location (b<sub>2</sub>) in Figure 8a contains much oxygen contamination as shown by decrease in C/O ratio (Figure 8b). This could be related to the high surface reactivity of the deformed region. Moreover, HR-XPS showed significant increase in sp<sup>3</sup>/sp<sup>2</sup> ratio to 1.88 and 1.09 (Figure 8c and 8e) in two different locations

1  
2  
3 indicated in optical image (Figure 8a). These values are much higher as compared to tribofilm  
4  
5 formed in AA-RT tribo-condition. Furthermore, the  $sp^3/sp^2$  value of 1.88 in deformed location is  
6  
7 higher than virgin film surface and this is possibly associated to the conversion of  $sp^2$  into  
8  
9 amorphization (a-C) and disordered  $sp^3$  (t-aC) phase in high vacuum condition. This evidence is  
10  
11 supported by phonon behavior of these phases analyzed by Raman spectroscopy (Figure 5). The  
12  
13 above mentioned phase transformation is realistic at high activation energy which is contributed  
14  
15 by the high frictional energy in HV-RT tribo-condition. The photoelectron shift of O1s peaks is  
16  
17 quite similar and comparable to the tribofilm formed in AA-RT tribo-condition, indicating  
18  
19 surface contamination during exposure to ambient atmosphere. However, changes in intensity  
20  
21 and photoelectron peak shift of C=O, C-O and C-OH groups are related to oxidation behavior of  
22  
23 the carbon.  
24  
25  
26  
27

28  
29 In survey spectra, C/O ratio is much higher 2.46 and 2.42 at two different locations of the  
30  
31 ball scar formed in HV-HT (Figure 9b) as compared to other two tribo-conditions. These are  
32  
33 located as (a<sub>1</sub>) and (a<sub>2</sub>) in Figure 9a, respectively. Furthermore, this ratio is comparable to film  
34  
35 surface exposed to high temperature (Figure S9a), signifying resistance to adsorption of oxygen  
36  
37 contamination in HV-HT tribo-condition. The residual oxygen contamination thermally desorbs  
38  
39 mainly in the high temperature and high vacuum condition due to the weakening of cohesive  
40  
41 barrier.  
42  
43

60

**Figure 9.** (a) Optical image of ball scar (HV-HT tribo-condition) locations: (a<sub>1</sub>) and (a<sub>2</sub>) and corresponding survey XPS spectra of (b<sub>1</sub>) and (b<sub>2</sub>), respectively; HR-XPS of C1s and O1s of (c and d) at location (a<sub>1</sub>) and (e and f) at locations (a<sub>2</sub>), respectively.

Interestingly, sp<sup>3</sup>/sp<sup>2</sup> ratio of tribofilm is reduced to 0.46 and 0.42 at two different locations of ball scar (Figure 9c and 9e) as indicated in the optical image (Figure 9a). These values are much lower than virgin film surface (Figure 2c) and directly indicate the significant conversion of sp<sup>3</sup> into sp<sup>2</sup> phase. Such conversion was also evident in AA-RT tribo-condition to some extent but high temperature is energetically favorable for such a transformation.<sup>60</sup> This was indicated by the

1  
2  
3 decrease in  $sp^3/sp^2$  value to 0.57 when the film was exposed to high temperature (Figure S9b).  
4  
5 Stress-induced conversion of  $sp^3$  into  $sp^2$  phase is dominating in AA-RT while stress and thermal  
6  
7 energy both are governing factors for such conversion in HV-HT tribo-condition. Chemical  
8  
9 characteristics of tribofilm in AA-RT and HV-HT are contrasting to HV-RT tribo-condition. The  
10  
11 amorphization was dominated in HV-RT while graphitization occurred in AA-RT and HV-HT  
12  
13 tribo-conditions. The conversion of ordered  $sp^2$  and  $sp^3$  phases after the amorphization was  
14  
15 restricted in HV-RT tribo-condition. However, nucleation of ordered carbon phase in AA-RT  
16  
17 and HV-HT was realistic due to the favorable activation energy. The contribution of functional  
18  
19 groups in C1s photoelectron shift is suppressed at location ( $a_2$ ) as indicated in Figure 9a and  
20  
21 corresponding spectra is shown in Figure 9e. The chemical shift of these functional groups in  
22  
23 O1s photoelectron is different at two different locations (Figure 9d and 9f) and these are  
24  
25 associated to the chemical affinity of surface.

33 **5. Tribology Mechanisms.** Friction and wear values of UNCD NW films significantly differ  
34  
35 depending upon the tribology test conditions (Figure 3). It is shown above that these values are  
36  
37 high in HV-RT and significantly lower in HV-HT and AA-RT tribo-conditions. These  
38  
39 contrasting behaviors could be explained by (a) passivation of carbon dangling bonds<sup>16,23</sup> and (b)  
40  
41 passivated graphitization mechanism at the sliding interfaces. Density functional theory  
42  
43 calculations demonstrated that dissociation of  $H_2$  and  $H_2O$  are energetically favorable for the  
44  
45 passivation of dangling bonds in diamond, leading to reduction in surface energy.<sup>61</sup> This fact is  
46  
47 also demonstrated experimentally using spectroscopic technique by Konicek *et al.* in UNCD  
48  
49 films at ambient atmosphere and room temperature tribological condition.<sup>16</sup> Moreover, low  
50  
51 friction of UNCD films at 200°C was obtained in ambient atmosphere and room temperature  
52

1  
2  
3 condition and this was explained by passivation mechanism.<sup>43</sup> However, dissociative passivation  
4 mechanism of dangling bonds by ambient atmospheric H<sub>2</sub> and H<sub>2</sub>O is restricted in high-vacuum  
5 tribo-condition (HV-RT). On the other hand, the HV-RT condition is governing factor for the  
6 transformation of diamond and graphitic phase into t-aC and a-C structure. This is mainly  
7 associated to tribo-contact stress and high frictional energy which restricts these carbon phases to  
8 nucleate into ordered chemical structure in the absence of passivating media. This evidence is  
9 clearly demonstrated by the Raman spectroscopy which showed increase in a-C and t-aC  
10 structure at the deformed ball scar (Figure 5). Moreover, XPS comprehensively showed large  
11 amount of sp<sup>3</sup> fraction at the deformed ball contact (Figure 8). This is schematically presented in  
12 Figure 10b and standard deviation of sp<sup>3</sup>/sp<sup>2</sup> value is given in Figure 10d which showed  
13 significantly large ratio. Moreover, Raman spectroscopy results showed termination of TPA  
14 phase from the tribolayer formed at ball scar (Figure 5c and 5d).

**Figure 10.** Schematic of carbon phase composition at tribologically deformed ball contact in (a) AA-RT (b) HV-RT and (c) HV-HT condition with the representation of typical HR-XPS and (d) bar graph of  $sp^3/sp^2$  and C/O ratio with standard deviation.

The experimental facts revealed that in HV-RT tribo-condition, sliding is dominated between a-C and t-aC structure which is known to occupy the large fraction of dangling bonds in high vacuum condition.<sup>62</sup> The dangling bonds of carbon atoms form covalent bonds across the sliding interfaces which greatly enhanced the shear resistance. Moreover, these phases do not exhibit lamellar lattice structure and hence do not have easy tangential shearing. This causes increase in friction coefficient and wear to significantly high value which ultimately leads to partial mechanical failure of film (Figure 3a). However, passivation of dangling bonds is

1  
2  
3 energetically favorable in AA-RT tribo-condition which results in low friction coefficient and  
4 high wear resistance. In this condition, it is believed that the dangling bonds are terminated with  
5 either –OH or –H due to the dissociation of atmospheric H<sub>2</sub>O.<sup>16,23,61</sup> This was supported by the  
6 increase in C–O and C=O bonding fractions.<sup>16</sup> To support this, our results also showed increase  
7 in oxygen and its functional groups inside the wear track in AA-RT condition (Figure 7).  
8 Moreover, passivation of dangling bonds stabilizes the chemically distorted tribolayer of a-C and  
9 t-aC into ordered sp<sup>2</sup> phase. Such a chemical distortion is occurred by mechanical deformation  
10 during sliding process. Here, TPA phase is preserved with its structure at contact interfaces. This  
11 evidence is clearly noticed by the XPS spectra (Figure 7) and also supported by the Raman  
12 spectroscopy (Figure 4c and 4d). In this condition, low friction and high wear resistance of  
13 UNCD NW film in AA-RT are governed by the passivation of dangling bonds and partial  
14 graphitization of tribolayer formed at the alumina ball. This is schematically presented in Figure  
15 10a. The bar graph in Figure 10d showed statistical evidence of sp<sup>3</sup> to sp<sup>2</sup> transformation. This  
16 indicates that the sliding occurs between the graphitized tribolayer of ball and UNCD NW film  
17 and passivation was dominating mechanism during the interaction of sliding surfaces.

36  
37

38 Friction coefficient and wear almost vanishes in HV-HT which is contrasting to HV-RT  
39 tribo-condition. In this case, atmospheric water vapor is restricted during tribology test and  
40 passivation mechanism of dangling bonds at contact interfaces is energetically not favorable.  
41 Therefore, in this condition, graphitization of the sliding interfaces can be considered for  
42 improving the tribological properties significantly.<sup>42</sup> The evidence of graphitized sliding  
43 interfaces is well investigated by Raman spectroscopy (Figure 6) and XPS (Figure 9). For clear  
44 understanding, graphitized ball scar is schematically given in Figure 10c and bar graph in Figure  
45 10d. This showed decrease in sp<sup>3</sup>/sp<sup>2</sup> in HR XPS and significant increase in C/O ratio in survey

3 spectra. The activation energy for graphitization is provided by film temperature during sliding  
4 process in high-temperature tribology condition. Here, frictional shear is dominated between  
5 hydrogenated graphitized interfaces that lead to ultra-low friction coefficient and wearless  
6 behavior. The hydrogen passivation of graphitized phases is intrinsically carried out by TPA  
7 phase as clearly observed by Raman spectroscopy (Figure 6). Basic mechanism which improved  
8 the tribological properties is governed by the unique lamellar lattice structure of hydrogenated  
9  $sp^2$  phase which is environment dependent<sup>63</sup> and shears easily with negligible tangential  
10 resistance. However, tribological properties of UNCD films at high temperature and ambient  
11 atmospheric condition were significantly degraded due to the oxidation which increases the shear  
12 resistance.<sup>43</sup>

## 23 24 25 26 27 28 **6. CONCLUSIONS**

29 Tribological properties of UNCD NW films were investigated in AA-RT, HV-RT and HV-HT  
30 tribo-conditions. HRTEM analysis directly showed ultranano diamond grains in the film which  
31 was further supported by the Raman spectroscopy. Moreover, phase composition was  
32 investigated by XPS analysis which showed significant amount of  $sp^3$  phase of ultranano  
33 diamond grains and grain boundary of UNCD occupied by a-C and  $sp^2$  phases. Furthermore,  
34 randomly oriented nanowall morphology of the films was analyzed by high-resolution SEM.  
35 Raman spectroscopy and XPS confirmed the mechanochemical conversion of UNCD phase and  
36 tribo-environment dependent changes in chemical characteristic of tribofilm at contact interfaces.  
37 Friction coefficient was significantly high  $\sim 0.17$  and wear induced film failure with wear loss of  
38 0.006 nm/cycles was observed in HV-RT condition. In this case, passivation mechanism was  
39 restricted and frictional shear transformed the diamond  $sp^3$  into a-C and t-aC phases. However,

1  
2  
3 passivation and graphitization were energetically favorable mechanisms in AA-RT tribo-  
4 condition which reduced the friction coefficient and wear up to ~0.023 and 0.002 nm/cycles,  
5  
6 respectively. Moreover, significant conversion of diamond  $sp^3$  into graphitized phase in the  
7  
8 presence of internal hydrogen of film was predominant mechanism for the superlow friction  
9  
10 coefficient ~0.002 and ultra high wear resistance of 0.0016 nm/cycles in HV-HT tribo-condition.
