#### **Abstract**

Semiconductor mediated photocatalysis represents an environmentally friendly technology that could be used for the degradation of different pollutants in the gas and aqueous phases, for hydrogen generation, as well as, for CO<sub>2</sub>-to-valuable product transformation reactions. Therefore, it is extremely important to accurately design a photocatalyst with the relevant features. In recent years, ionic liquids have often been employed as reagents for the synthesis of these materials. To address the issue of semiconductor-based photocatalytic preparation in the presence of ionic liquids, eight main paths of interaction between ionic liquid with the formed semiconductor particles in the solvothermal process were identified and described based on literature examples. The most critical aspects discussed here are understanding how an ionic liquid may behave during the solvothermal synthesis of semiconductor material particles and how its behavior may ultimately affect the properties of that material, as well as what techniques are available that allow us to assess the nature of this interaction mechanism.

#### Introduction

Semiconductor mediated photocatalysis utilizes the energy of light to activate a large number of chemical reactions that are thermodynamically uphill reactions under normal conditions, such as pollutant degradation in the gas and liquid phase, hydrogen generation, and  $CO_2$  photoconversion. To optimize reaction conditions and to enhance the efficiency of the abovementioned reactions a wide spectrum of semiconductors materials have been applied, including metal oxides (e.g.  $TiO_2$ , ZnO), metal chalcogenides (ZnS, CdS, CdSe, carbon nitride-based materials (g-C<sub>3</sub>N<sub>4</sub>), bismuth oxyhalides (BiOX, where X = F, Cl, Br, I), perovskite oxides (ABO<sub>3</sub>), metal halide perovskites and double perovskites. The photocatalytic performance of those materials is affected by their structural and surface properties, such as:

- (i) morphology;
- (ii) surface area and porosity;
- (iii) surface composition (dopants, vacancies, impurities);
- (iv) electronic band structure (position of valence and conduction band edges and band gap value).

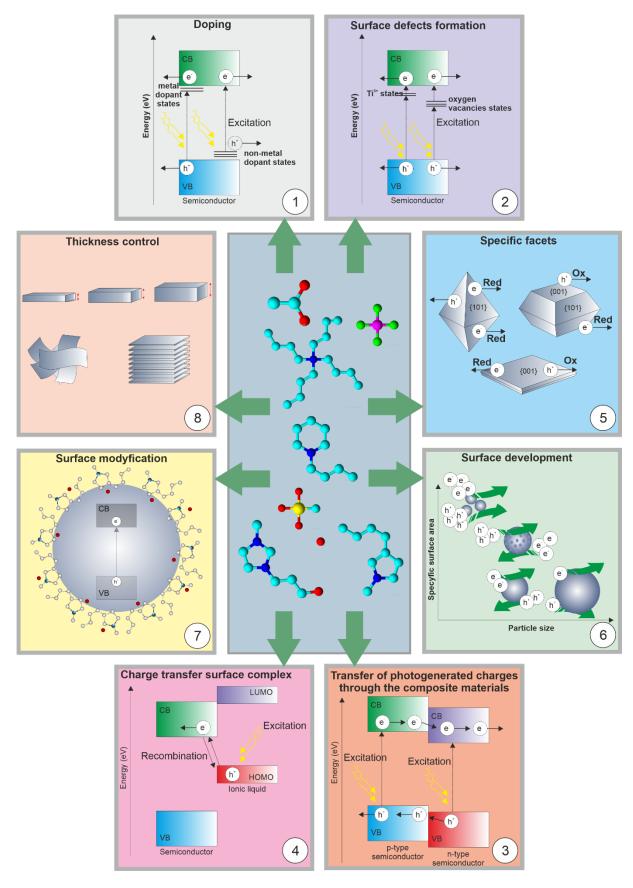

On the other hand, the above-mentioned properties could be designed throughout the introduction of ionic liquids (ILs) during semiconductor particle synthesis. ILs are usually built of large, organic cations and smaller anions, and due to their structure. ionic liquids could interact both with themselves and with other components during the synthesis of nanoand micromaterials. It is known that ILs could play the role of structuring agent through one of the following mechanisms: (i) stabilization of growing particles by the formation of a protective layer; (ii) stabilization of growing particles by higher viscosity of the ILs; (iii) interaction between growing particles and fluoride anions generated in situ throughout hydrolysis of IL containing [BF<sub>4</sub>] and [PF<sub>6</sub>] anions; (iv) ILs-based micellar aggregates employed as nanoreactors or soft templates; (v) agent promoting reduction of particles' precursor; and (vi) soft template for growing particles <sup>1</sup>. Moreover, for TiO<sub>2</sub> particles obtained in the presence of ionic liquids, it was found that the introduction of ILs during the synthesis of semiconductor material could affect their photocatalytic properties <sup>2–9</sup>. Our previous investigation has shown that ionic liquids could induce visible light activity of wide bandgap semiconductors such as TiO<sub>2</sub>. Two main mechanisms have been pointed out to be responsible for this photoactivity: (i) formation of surface complex between ILs and TiO2; and (ii) generating of mid-bandgap level in the structure of TiO2 by interaction with non-metal dopants evolved from ionic liquids 10. These mechanisms of visible light activity induction have been correlated with the stability of the ionic liquids during the solvothermal synthesis of TiO<sub>2</sub>. Based on both experimental data and chemoinformatic analysis regarding TiO<sub>2</sub> synthesized in the presence of 23 different ionic liquids, it was found the dependency between the chemical structure of the ionic liquid, its durability at elevated temperature (e.g. condition of solvothermal synthesis) and type mechanism visible light induced photoactivity of finally obtained ILs-TiO<sub>2</sub>. Generally, we can conclude that stable ionic liquids (not decomposed during solvothermal synthesis of TiO<sub>2</sub>) could contribute into the formation of a chargetransfer (CT) complex between titania facial and adsorbed IL, while unstable ionic liquids (decomposed during solvothermal synthesis of TiO<sub>2</sub>) could provide a non-metal atoms to be built into TiO<sub>2</sub> structure as dopants. The effect of ILs on the surface electronic properties of TiO<sub>2</sub> was also cleared up by using the reversed double-beam photoacoustic spectroscopy (RDB-PAS) technique, developed by the Ohtani research group 11. These measurements added new information, namely the energy-resolved distribution of electron trap (ERDT) and conduction band bottom (CBB), that had not been previously noticed using conventional analysis such as X-ray powder diffraction (XRD) and X-ray photoelectron spectroscopy (XPS). Thus, RDB-PAS demonstrated that ILs are able to promote the formation of a surface amorphous layer shielded by hydrophobic organic residues, resulting in higher adsorption of phenol on the surface and finally higher efficiency of phenol degradation under visible light

Considering the great practical pertinence of the application of ionic liquids for semiconducting photocatalyst preparation, there is already extensive literature on this topic. However, several previous reviews have focused only on selected aspects of these phenomena. Duan at al. <sup>13</sup> collected data on the employment of ILs as the reactant, solvent, and surfactant during the preparation of functional inorganic materials and then tried to verify whether it was an anion or cation from ionic liquids is nearby to the liquid-solid interface between ILs and fabricated material. Benefits of the usage of ILs compared to the employment of Deep Eutectic Solvents (DES) have been presented for the fabrication of both nanostructured TiO<sub>2</sub> <sup>14</sup> and a wider group of nanomaterials <sup>15</sup>. Property modulation of two-dimensional (2D) materials by ILs introduced during synthesis was discussed in relation to materials obtained by exfoliation, application of ILs as the gating layer to increase charge carrier density, as well as usage of ILs to fabricate 2D material electrodes and to boost crystallization process of perovskites in photovoltaic cells <sup>16</sup>.

In this review, we collected literature on the preparation of semiconductor photocatalysts in the presence of ionic liquids and, on this basis, we determined the main mechanism for inducing photoactivity of the obtained materials, related to the presence of ionic liquids. The gathered data showed us that there are eight main ways in which ionic liquids can increase the photoactivity of semiconductors both when excited by UV and Vis radiation. As presented in Figure 1, ILs could control photoactivity throughout:

- 1. creation of new energy states by doping elements originated from ionic liquid (dopant presence could provoke an apparent narrowing of the semiconductor band gap and/or inhibit electrons and holes recombination);
- 2. surface defect formation throughout interaction between ionic liquid and growing semiconductor particles (surface defects affect recombination of photoinduced electron-hole pairs, cause an apparent narrowing of the semiconductor band gap, and provide additional active sites for catalytic reactions);
- 3. facilitating the charge transfer by enabling the formation of heterojunction in composite materials;
- 4. presence of surface complex able to absorb visible light throughout adsorption and chemical interactions between ionic liquids and semiconductor outer;
- 5. creation of specific facets beneficial for photocatalytic reaction;
- 6. affecting semiconductor particles size and porosity;
- 7. surface modification by the presence of ionic liquids at the surface of semiconductor materials affecting the interaction between the semiconductor surface and components of the reaction mixture (e.g. sorption properties);
- 8. controlling the thickness of synthesized materials towards obtaining ultrathin 2D materials (it results in shorter diffusion paths, faster charge carrier transport, and finally reduces the likelihood of charge carriers recombination).

Tables 1 to 8 present data collected from selected research articles regarding semiconductor photocatalysts manufacturing in the presence of ionic liquids. We decided to compile the data only from articles on the basis of which it is possible to clearly determine how the ionic liquids affect the photoactivity of the obtained semiconductor. In the following sections, we briefly discuss the principles of each of the mechanisms presented in Figure 1 and mentioned above with reference to specific examples. In the final part of each section, "known" and "unknown" facts regarding the specific impact of ionic liquids on the presented photoexcitation mechanism are summarized.

**Figure 1.** The main paths in which ionic liquids impact the properties of semiconductors and the mechanism of their photoexcitation

# 1) Doping elements originated from ionic liquid

Semiconductors with weak visible-light activity (i.e. having a bandgap  $\geq 3$  eV) can be modified by metallic or non-metallic elements to extend the wavelength of photoabsorption towards the visible region. The term "doping" means the incorporation of atoms or ions into the material's crystal lattice, that is, modification of the bulk structure of crystallites, but not modification of the surface<sup>17</sup>. The dopants, either through substitution or interstitial doping (or both), modulate the material's electronic structure. Doping may induce the formation of local intraband energy states (e.g. oxygen vacancy, OV) that become centers of optical excitation and relaxation<sup>18,19</sup>. These states should overlap with the band states of the semiconductor to transfer photoexcited carriers to the reactive sites at the catalyst surface within their lifetime<sup>20</sup>. Excitations from the localized states to conduction band (CB) may account for the extended absorption tail of absorption curve to the longer wavelengths with respect to undoped semiconductors (UV region)<sup>21</sup>. Another effect caused by doping is shifting the position of the conduction or valence band (VB), thereby narrowing the bandgap without introduction of any local states. In this case, a red-shift of the entire absorption edge toward the longer wavelength is observed, which favorably affects both light absorption and photocatalytic activity<sup>22</sup>. Absorption in the visible light region can also be attributed to dopant-induced defects, including surface reconstruction<sup>23</sup> and lower recombination rate of charge carriers<sup>24</sup>.

Ionic liquid is most often used as an additive to the reaction medium in which the semiconductor is obtained. If IL decomposes under the synthesis conditions used, it becomes a source of non-metallic, e.g., B<sup>25,26</sup>, N <sup>7,27,28</sup>, F<sup>29</sup>, I<sup>30</sup>, P <sup>31</sup>, C<sup>26,28,32</sup>, S<sup>33</sup>, Cl <sup>34</sup> or metallic species Fe <sup>17,35</sup> which may be embedded in the semiconductor structure. Studies conducted so far (summarized in Table 1) indicate that doped elements (one or more) were derived from the decomposition of the following ILs' cations: 1-ethyl-3-methylimidazolium<sup>28,29,36</sup>, 1-butyl-3-methylimidazolium<sup>25–27,30,31,33</sup>, 1-methyl-3-octylimidazolium<sup>34,35,37</sup>, 1-butylpyridinium<sup>7</sup> or the ILs' anions: tetrafluoroborate<sup>25–27,29</sup>, hexafluorophosphate<sup>31</sup>, tetrachloroferrate<sup>34,35</sup>, iodide<sup>30</sup>, chloride<sup>7,28,33,36</sup>.

Doping of elements in the crystal lattice can be proved through various techniques such as XPS (analysis of valency of doped elements)<sup>17</sup>, XRD (shifts in diffraction peaks)<sup>38</sup>, UV-vis absorbance spectra<sup>39</sup>, or first-principles calculations<sup>20</sup>, whereas photocatalysis by doped photocatalysts by the action spectrum analysis (analysis of resemblance of absorption and actions spectra)<sup>40</sup>. Yu et al. <sup>26</sup> used the XPS technique to confirm the substitutional (signal at 197.0 eV) and interstitial (signal at 193.6 eV) doping of B atoms derived from 1-butyl-3methylimidazolium tetrafluoroborate into the TiO<sub>2</sub> lattice (formation of B-Ti species). In addition, the peak at 281.1 eV was assigned to the O-Ti-C bonds, resulting from the substitution of the oxygen atom with carbon. The XPS analysis also revealed the presence of the Ti<sup>3+</sup> species in the titania structure, which according to the authors, facilitates the transition of photogenerated electrons and reduces the electron-hole recombination rate. However, the UV-Vis spectra performed for this material did not reveal a redshift of the absorption, which was concluded by the lack of band narrowing in doped TiO<sub>2</sub>. The shift of the absorption edge toward the higher wavelength, in contrast, was observed for F-doped Pt/TiO<sub>2</sub> <sup>29</sup> (1-ethyl-3-methylimidazolium tetrafluoroborate was a source of fluoride) and Ndoped TiO<sub>2</sub> <sup>28,36</sup> (N was derived from 1-ethyl-3-methylimidazolium chloride) compared to P25 TiO<sub>2</sub> used as a reference material.

*Known:* methods of using IL to incorporate non-metals into semiconductor lattices; examples of IL susceptible to decomposition during synthesis and being a source of dopants.

*Unknown:* effect of the IL-derived doping on the electronic structure of the material (band gap narrowing and/or localized states formation); conditions under which IL-derived mono- and codoping occurs; amount and distribution of doped elements, stability of the doped material under photocatalytic reaction condition, possibility of surface reconstruction.

Table 1. Category: doping. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*,\*\*.

- surface properties: diameter ( $\varphi$ ), thickness (th), length (l), width (w), crystallite size (D) specific surface area ( $S_{BET}$ ), pore volume ( $V_p$ ), pore size ( $\varphi_p$ ), aspect ratio,
- conditions: photocatalyst content (Cphot), the concentration of model pollutant (C0), sacrificial agent (sacr. agent), volume of solution (Vs), irradiation time (t),
- efficiency: yield (Y)/rate (r)/rate constant (k) of the most active sample (Y), and the reference sample (Yref),  $\nearrow$  increase, and  $\searrow$  decrease compared to the reference sample.

#### 2) Surface defects formation

The atomic structure of photocatalysts, when disrupted or compromised, can lead to the formation of defects that can play a crucial role in influencing their optical, electronic, and photocatalytic properties. Defects (e.g., oxygen, and sulfur vacancies) can act as active sites for photocatalytic reactions. This enhancement stems from the defects' ability to curtail the recombination of photoinduced electron-hole pairs, narrow the energy band, and provide additional active sites for catalytic reactions<sup>41</sup>. Among the most prevalent defects in oxide photocatalysts are oxygen vacancies (OVs), typically intrinsic in nature. These vacancies form when oxygen atoms within the crystalline structure undergo partial reduction, introducing two extra electrons<sup>42</sup>. The generation of OVs can occur during crystal growth, through the introduction of dopants, or as a consequence of specific crystal phase formations. Manipulating the concentration of OVs within photocatalysts is achievable through various means, such as modifying synthesis conditions employing post-synthesis treatments like annealing at specific temperatures, adjusting synthesis atmospheres, or subjecting the material to irradiation. These strategies offer a feasible approach to control and regulate the concentration of OVs, thereby influencing the overall photocatalytic performance of the material.

The role of ILs in the synthesis of TiO<sub>2</sub> materials wherein the interaction between the ILs and TiO<sub>2</sub> induces the intentional formation of oxygen vacancies has gained much attention. The induction of oxygen vacancies in TiO<sub>2</sub> is a pivotal step in the generation of Ti<sup>3+</sup> species. So far, ILs such as 1-decyl-3-methylimidazolium chloride<sup>2</sup>, 1-benzyl-3-methylimidazolium chloride<sup>7</sup>, 1-butyl-1-metylpyrrolidinium chloride<sup>7</sup>, 1-butylpyridinium chloride<sup>7</sup>, tetrafluoroborate<sup>43</sup>, chloride<sup>7</sup>, tetrabutylammonium 1-methylimidazolium 1-butyl-3methylimidazolium tetrafluoroborate<sup>3,44,45</sup>, 1-butyl-3-methylimidazolium chloride<sup>2,44</sup>, 1-ethyl-3-methylimidazolium tetrafluoroborate<sup>3</sup>, and 1-methyl-3-octylimidazolium tetrafluoroborate<sup>3</sup> have been used.

The formation of defects on the surface of other photocatalysts (e.g., ZnO, BiOBr, BiOI, BiVO<sub>4</sub>) has been observed in the presence of 1-ethyl-3-methylimidazolium bromide<sup>46</sup>, 1butyl-3-methylimidazolium bromide<sup>46</sup>, 1-hexyl-3-methylimidazolium bromide<sup>46</sup>, 1-methylbromide<sup>46–48</sup>, chloride<sup>49</sup>. 3-octvlimidazolium 1-hexadecyl-3-methylimidazolium hydroxide<sup>50</sup>, tetrabutylphosphonium hydroxide<sup>51</sup>, tetrabutylammonium methylimidazolium bromide<sup>47,48</sup>, 1-dodecyl-3-methylimidazolium bromide<sup>47,48</sup>, 1-butyl-3methylimidazolium tetrafluoroborate<sup>48</sup>, 1-butyl-3-methylimidazolium hexafluorophosphate<sup>48</sup>, bromide<sup>52</sup>, 1-octyl-3-methylimidazolium 1-methoxyethyl-3-methylimidazolium trichloride<sup>53</sup>, 3-butyl-1-methylimidazolium tetrachlorobismate<sup>54</sup>, 3-butyl-1methylimidazolium vanadate<sup>54</sup>, 3-(2-methoxyethyl)-1-methylimidazolium 3-(2-methoxyethyl)-1-methylimidazolium tetrachlorobismate<sup>54</sup>, vanadate<sup>54</sup>, methylimidazolium iodide<sup>55</sup>, 1-ethyl-3-methylimidazolium dihydrogen phosphate<sup>56</sup>, 1-butyl-3-methylimidazolium chloride<sup>49</sup>, and 1-ethyl-3-methylimidazolium tetrafluoroborate<sup>57</sup>. Within Table 2, we have highlighted various examples where ILs have contributed to creating defects or local distortions.

The influence of ILs on the formation of defects was corroborated and validated through multiple spectroscopic techniques, including Electron Paramagnetic Resonance (EPR), Electron Spin Resonance (ESR), Photoluminescence (PL) spectroscopy, and XPS. Based on them, it can be stated that the surface defects, specifically Ti<sup>3+</sup>, are attributed to the contribution of ILs, both imidazolium<sup>2,44</sup>, and non-imidazolium ones<sup>7</sup>. The ILs contribute to incorporating Ti<sup>3+</sup>into the bulk TiO<sub>2</sub> through the partial decomposition of the imidazolium cation and the hydrolysis of anion<sup>43</sup>. The partial decomposition of ILs results in the co-

adsorption of decomposed elements and surface modification (e.g., Ti-O-N species)<sup>3,7,45</sup>. This indicates that ILs are involved in the initial stages of synthesis and influence the composition of the final TiO<sub>2</sub> product. It is confirmed that the IL precursor plays a pivotal role in dictating the morphology, and crystallinity, and the growth mechanism is intricately linked to electrostatic interactions with IL cations<sup>46,50,52</sup>. The incorporation of ILs enhances photocatalytic performance through the formation of defects and the influence of alkyl chain size<sup>49,54</sup>.

However, in the case of other photocatalysts than TiO<sub>2</sub>, the role and importance of the use of ILs in relation to the defects is much less discussed. It is unclear on what basis ILs, which potentially contribute to the formation of defects, while their interaction with precursor materials and reaction conditions may influence the defect formation process, are selected. There is a lack of information about the behavior of ILs in the reaction medium. Understanding the fate of ILs during the synthesis process and developing methods to remove any residual ILs or by-products is crucial for ensuring the purity and functionality of the final materials. Further research in this area is essential to understand the dynamics of ILs during synthesis, their impact on defect formation, and the steps needed to ensure the removal of any residual ILs.

*Known*: contribute to surface defects formation (particularly Ti<sup>3+</sup>); facilitate the incorporation of Ti<sup>3+</sup> into bulk TiO<sub>2</sub> through imidazolium cation decomposition and anion hydrolysis; partial IL decomposition leads to co-adsorption (Ti-O-N species); influence the initial synthesis stages, shaping the composition of the final product; determines morphology, crystallinity, and growth mechanism via electrostatic interactions.

*Unknown*: role in formation and photoactivity other than TiO<sub>2</sub> photocatalysts; basis for ILs selection (what properties are the most important, how they interact with precursor materials, and how reaction conditions influences the defect formation process).

Table 2. Category: surface defects formation. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*, \*\*.

- surface properties: shape (s), diameter (φ), thickness (th), length (l), width (w), crystallite size (D) specific surface area (S<sub>BET</sub>), pore volume (V<sub>p</sub>), pore size (φ<sub>p</sub>), aspect ratio,
- conditions: photocatalyst content (mphot), the concentration of model pollutant (C<sub>0</sub>), sacrificial agent (sacr. agent), volume of solution (Vs), irradiation time (t),
- efficiency: yield (Y)/rate (r)/rate constant (k) of the most active sample (Yphot), and the reference sample (Yref), > increase, and > decrease compared to the reference sample.

<sup>\*\*</sup>The original sample label is given in italics.

# 3) Transfer of photogenerated charges through the composite materials

One of the methods for improving migration process of the photogenerated electrons and holes, is the creation of a heterojunction by connecting two semiconducting materials. The mentioned moieties must be present on the surface of the photocatalyst to efficiently take part in the ongoing reactions by producing reactive species necessary for the photocatalytic process – like for example hydroxyl radicals<sup>59</sup> or superoxide anions<sup>60</sup>. Thus, one of the main factors influencing photocatalytic activity is the efficient transport of photogenerated charge to the surface of the material. If two materials possess compatible locations of conduction and valence bands, such conjugation, as creation of a heterojunction, can lead to a widening of the range of light absorption and reduction of charge recombination probability. In the case of type II heterojunction, the electrons generated after light irradiation are injected into the CB of the p-type semiconductor, to further migrate to the CB of the n-type semiconductor because of internal electric field activity. At the same time, the created holes can migrate from the VB of n-type semiconductor to the VB of p-type semiconductor, which assures their separation from the electrons and prevents recombination. The decreased rate of charge recombination can be confirmed by methods like electrochemical impedance spectroscopy (EIS)<sup>61</sup>, surface photovoltage spectroscopy (SPS)<sup>62</sup> or PL<sup>60</sup>.

The addition of ILs to the synthesis environment was found to facilitate the creation of heterojunctions, thus to the Fermi level alignment at the interface of the materials, because of the changes in individual energy bands' location. This enables the suitable transfer of charges within the so-connected bands, which cannot be observed when two materials are only mechanically mixed, as the particles are not tightly adhered to each other<sup>63</sup>. Furthermore, the presence of ILs promotes the formation of crystalline phases<sup>64</sup>, as well as contributes to the regular dispersity of phases<sup>65–67</sup> and the creation of morphology beneficial for photocatalytic processes (like flake-like<sup>66</sup> shape or nano-flowers aggregated from thin sheets<sup>65</sup>). Among the researched materials, different bismuth oxyhalides (BiOX) and their composites were synthesized by using halide-based ILs as halide precursors. In identical conditions, the replacement of IL with simple salt (e.g., KCl instead of 1-butyl-3-methylimidazolium chloride<sup>64</sup>) did not lead to the obtainment of a composite, but only of BiOX of poor crystallinity instead. The positive polarity of ILs can also facilitate the connection of material characterized by negative polarity with other semiconductors, because of electrostatic attraction<sup>60,68</sup>.

The decreased rate of photogenerated charge recombination in studied materials was observed particularly in the assistance of halide-based ILs, of which the anion was playing the role of reagent. The chloride<sup>63,64,68-73</sup>, bromide<sup>61,65,72,74-82</sup>, and iodide<sup>67,78,83-86</sup> anions of ILs were most often with imidazolium-based paired different cations for example 1-propyl-3methylimidazolium<sup>78,83</sup>, 1-allyl-3-methylimidazolium<sup>73</sup>, 1-butyl-3-methylimidazolium<sup>64,67,76,86,87</sup>, 1-methyl-3-octylimidazolium<sup>60,61,74</sup>, 1-hexyl-3-methylimidazolium<sup>63,84,85</sup>,  $methylimidazolium^{65,68,71,72,75,79-82}$ 1-methyl-3-[3'-(trimethoxysilyl)propyl]-imidazolium<sup>70</sup>. or Among others, ILs possessing cations like N-methyl-2-pyrrolidonium<sup>69</sup>, diethylamine<sup>66</sup>, tetrabutylammonium<sup>77</sup>, tetrachloroferrate<sup>61</sup> or N-butyl-N-methylpiperidinium<sup>61</sup>, and anions like dihydrogen phosphate<sup>60</sup>, hydrochloride<sup>66</sup> as well as tetrafluoroborate<sup>87</sup>, were also utilized. The details of the collected data are presented in Table 3.

Formation of composites in presence of ILs was widely described as a result of their efficient binding and structure-directing abilities. This was further described as the origin of photocatalytic abilities improvement of the as-synthesized materials. Photocurrent measurement <sup>64,65,67,69–72,75–77,79–87</sup>, Electrochemical Impedance Spectroscopy (EIS) <sup>60,61,65,67,70–</sup>

<sup>73,75–77,79–86</sup>, SPS <sup>66,69,78,83</sup>, and PL <sup>60,61,63,65,67,70–73,75–77,79–82,84–86</sup> can confirm the decreased rate of charge recombination, and thus the enhanced catalytic efficiency. However, there exist several 'white spots', which should be noted and focused in further research. First concerns limited data regarding confirmation whether the ionic liquid remains at the surface of the photocatalyst, and thus taking part in the light-driven reaction and influencing its mechanism. The presence, or the absence, of ILs on the photocatalyst surface is usually only determined by Fourier-Transform Infrared Spectroscopy (FTIR) <sup>60,63,64,74,79,81,82,84,85</sup>. The second, concerns utilization of halide-based ILs. There is limited information concerning the validity of their use instead of simple halides precursors, especially in terms of bismuth oxyhalides synthesis. Additionally, even though there were various ILs investigated in this field, the vast majority of research is concerning the use of the most popular imidazolium-based ILs. The data regarding other types of ILs is still hardly explored.

Known: ILs are capable of playing the role of reactive structure-directing agents during synthesis of composites

*Unknow:* exact influence of ILs on photocatalytic reaction mechanism; insufficient investigation over presence of ILs remaining on the surface of the catalyst and its participation in the photocatalytic reaction.

**Table 3.** Category: transfer of photogenerated charges through the composite materials. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*,\*\*.

- surface properties: diameter (φ), thickness (th), length (l), width (w), crystallite size (D), specific surface area (S<sub>BET</sub>), pore volume (V<sub>p</sub>), aspect ratio,
- conditions: photocatalyst content (C<sub>phot</sub>), concentration of model pollutant (C<sub>0</sub>), volume of solution (V<sub>s</sub>), irradiation time (t),
- efficiency: efficiency of the most active sample (E<sub>p</sub>), efficiency of the reference sample (E<sub>ref</sub>), ≯ increase, and ১ decrease compared to reference sample.

### 4) Formation of charge-transfer (CT) surface complex

A semiconductor photocatalyst agitated by visible light may be created as a result of interaction between the wide bandgap semiconductor and an organic compound adsorbed on its surface – both of which do not absorb radiation in the visible range. In this occurrence, a charge-transfer (CT) complex between an electron acceptor (semiconductor) and an electron donor (surface adsorbate) may be formed <sup>88</sup>. Surface complexes often consist of a transition metal ion and/or inorganic/organic ligands. Facial of the semiconductor is linked to the adsorbate through various anchors, which can be hydroxyl, carboxyl, amino, and other groups in the case of organic ligands or, for example, CN<sup>-</sup>, F<sup>-</sup>, PO<sub>4</sub><sup>3-</sup> in the case of inorganic ligands<sup>89</sup>. Within this mechanism, also called a CT-sensitization or ligand-to-metal charge transfer (LMCT), a direct charge-transfer excitation occurs with no significant involvement of an intermediate excited state (which is common for dye sensitization). In the case of n-type semiconductors (e.g. TiO<sub>2</sub>), the localized orbitals of the adsorbate are electronically coupled with empty surface states of the semiconductor. Excitation of the surface complex leads to optical electron transfer from the surface molecule ( $\pi$  electron of the highest occupied molecular orbital, HOMO) to the semiconductor CB ( $\pi \rightarrow$  CB) resulting in a decrease in the effective band gap energy of the semiconductor <sup>90,91</sup>. The resulting surface states with HOMO and LUMO characters are mostly located at the adsorbate and belong to the conduction band, respectively.

Since the holes are localized in the organic modifier, and the electrons in the CB of the semiconductor, the hole-electron recombination is prevented, and the lifetime of separated photogenerated charges is extended<sup>90</sup>. Characterization of the surface complex formation is not easy and can be determined by the combination of experimental and theoretical techniques such as UV-visible absorption<sup>92</sup>, diffuse reflection (DR)<sup>93</sup>, VIS-NIR<sup>94</sup>, Attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR)<sup>95</sup>, UV photoemission spectroscopy (UPS), and scanning tunneling microscopy (STM)<sup>96</sup> and quantum chemical calculations<sup>90,97</sup>. In the case of the IL-semiconductor systems, quantum chemical calculations<sup>98</sup> on an anatase vacancy model showed that interactions between halogens (IL anion) and OV are responsible for the excitation of TiO<sub>2</sub> under Vis radiation. The formation of OV on TiO2, equivalent to the appearance of the Ti3+ centers, leads to the formation of unpaired electrons that can form donor levels in the electron structure of TiO2. The charge transfer between the bromide anion of IL (1-butyl-3-methylimidazolium bromide4 or 1butylpyridinium bromide<sup>98</sup>) and molecular oxygen interacting with the vacancy on the TiO<sub>2</sub> surface to form the surface complex (O2···Br dimer on a TiO2 vacancy) is a source of is photon-induced photoactivity. Theoretical calculations and experimental research (the apparent quantum efficiency of the photocatalysts) confirmed the presence of a charge transfer complex with a maximum absorption band of about 448 nm for TiO<sub>2</sub> prepared in a presence 1-butyl-3-methylimidazolium bromide. The leading transition (>90%) of 448 nm excitation corresponds to the excitation of an electron from the lone pair in the bromide anion to the  $\pi^*$  orbital localized in the oxygen molecule <sup>98</sup>. FTIR spectra taken for TiO<sub>2</sub> modified by 1-butyl-3-methylimidazolium hydroxide<sup>99</sup> revealed the bands at 1395 cm<sup>-1</sup> (bending vibrations of -CH<sub>3</sub> and -CH<sub>2</sub>-,), at 2852 and 2920 cm<sup>-1</sup> (stretching vibrations of aliphatic C-H bonds), which were not present in reference TiO<sub>2</sub>. Moreover, comparing the peak areas at 529.9 and 531.8 eV in the O 1 s region obtained from the XPS study, the authors concluded that the decreased number of the surface hydroxyl groups (Ti-OH) is due to the formation of the surface complex between TiO<sub>2</sub> and 1-butyl-3-methylimidazolium hydroxide (Ti-O-C bond formation).

For the semiconductors synthesized in the presence of ionic liquids, the surface complex formation was concluded for the TiO2 and ZnS photocatalysts with the following ILs: 1hydroxide<sup>99</sup>, chloride<sup>2</sup>, chloride<sup>98</sup>, 1-butyl-3-methylimidazolium butylpyridinium 1-butyl-3nitrate 100, 1-butyl-3-methylimidazolium methylimidazolium 1-decyl-3methylimidazolium chloride<sup>2</sup>, 1-methyl-3-octylimidazolium hexafluorophosphate<sup>101</sup>, and 1butyl-3-methylimidazolium bromide<sup>4</sup> as shown in Table 4. Analysis of the electronic structure of ILs revealed that in the case of 1-alkyl-3-methylimidazolium derivatives with halogens as anions, HOMO is localized on the anion whereas in fluorinated ILs HOMO level is associated with the cation or both ions 102-104.

Known: localization of HOMO in ionic liquids

*Unknown:* geometry of the CT complexes, effect of the IL-derived CT complex on the electronic structure of the semiconductor (new energy levels), energy of charge transfer, correlations between structures of complexes and applicability for photocatalysis, stability of the complexes.

**Table 4.** Category: formation of charge transfer (CT) surface complex. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*,\*\*.

- surface properties: diameter  $(\phi)$ , thickness (th), length (l), width (w), crystallite size (D) specific surface area  $(S_{BET})$ , pore volume  $(V_p)$ , pore size  $(\phi_p)$ , aspect ratio,
- condition: photocatalyst content (C<sub>phot</sub>), concentration of model pollutant (C<sub>0</sub>), sacrificial agent (sacr. agent), volume of solution (Vs), irradiation time (t),
- efficiency: yield (Y)/rate (r)/rate constant (k) of the most active sample (Y), and the reference sample ( $Y_{ref}$ ),  $\nearrow$  increase, and  $\searrow$  decrease compared to the reference sample.

## 5) Exposing crystallographic planes

The exposition of specific crystallographic facets or the presence of different phases of one compound (thus the presence of specific facets) can significantly influence the photocatalytic abilities of different crystalline materials. High exposure to specific planes may be beneficial for the increased pollution particles' adsorption capacity. This is due to the presence of a high amount of under-coordinated sites, that are characterized by greater reactivity in comparison with other planes<sup>105</sup>, as the molecules in photocatalysis-favorable states can be easily accessed by the particles of contaminants<sup>106</sup>. What is more, the presence of two specific facets can significantly suppress the recombination of photogenerated electron-hole pairs<sup>107</sup>. The reactions of reduction and oxidation can occur on different planes because of their different band structure, as well as the varying positions of the edges of the bands. This leads to the separation of the electrons and holes which are transported to distinct planes<sup>105,108</sup>. The formation of particular facets and their content can be determined by using methods like transmission electron microscopy (TEM) coupled with selected area electron diffraction (SAED)<sup>109</sup> or XRD<sup>110</sup>.

The most beneficial form of the growing crystal is one of the possibly lowest surface energies. However, the facets providing reactive centers are characterized by higher surface energy, which makes them unstable. The ILs' ability of weak interaction creation (like hydrogen bonding) can be a useful tool to influence the nucleation and further growth of crystalline solids, because of modified surface energy. This is an effect of the high polarity of ILs, thus low interface tension<sup>111</sup>. Such properties are vital to affecting the growth rate of different planes, as well as the order and arrangement of the unit cell connection. It is possible because of the presence of the weakly-bonded ILs particles present at specific surfaces<sup>112</sup> or edges<sup>110</sup>.

Imidazolium-based ILs were mainly utilized to obtain specified crystalline products. Among them ILs like 3-methyl-1-(3-sulfonylpropyl) imidazolium trifluoromethanesulfonate<sup>113</sup>, 1-(3hydroxypropyl)-3-methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>114</sup>, 1-buty1-3methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>114</sup>, 1-hexadecyl-3-methylimidazolium bromide<sup>112</sup>, 1-hexadecyl-3-methylimidazolium chloride<sup>112</sup>, 1-ethyl-3-methylimidazolium tetrafluoroborate<sup>115</sup>, 1-butyl-3-methylimidazolium bromide109, and 1-butyl-3methylimidazolium tetrafluoroborate<sup>110</sup> can be distinguished. Additionally, papers describing ILs possessing other types of cations like 1-butylpyridinium bis(trifluoromethylsulfonyl)imide114, 2-hydroxylethylammonium formate116 or tetradecyltrihexyl phosphonium bis(trifluoromethylsulfonyl)imide<sup>114</sup> were also presented. All the listed ILs are shown in Table 5.

High exposure of specific planes may be beneficial for the increased pollution particles adsorption capacity. In case of bismuth oxyhalides, exposition of {001} facets, resulting in sheet-like structures, can be achieved by introduction of halide-based ILs as the halide source 109,112. At the same time, the cations of the ILs interact with the oxygen atoms of forming structure net by creation of hydrogen bonding. This process leads to decrease of surface energy of the mentioned facet hindering its growth. Additionally, the manipulation with specific planes growth was connected with improvement of electron-holes separation, when the (002) and (222) facets of NH<sub>2</sub>-MIL-125(Ti) were exposed in the fabricated composite 115. In turn, in case of SrTiO<sub>3</sub> it was established that the functionalization of side chain of imidazolate IL can affect the growth in different directions, thus influence the photocatalytic efficiency 114.

As the literature shows, the influence of ILs on forming structure, and thus on the facets being exposed, as well as on the presence of different phases, can be easily confirmed by abovementioned methods<sup>109,110</sup>. The structure-directing abilities of ILs can be verified, by comparison of the material with the reference sample obtained when no IL is added to the reaction environment. However, the information regarding the presence of IL residues on the surface of the catalyst is not always provided. This can raise a question about the participation of IL (or its decomposition products) in photocatalytic process and how does it affect the mechanism of the reaction.

*Known:* ILs are capable of playing the role of reactive structure-directing agents, and thus affect the electron-hole separation

*Unknown:* exact influence of ILs on photocatalytic reaction mechanism; insufficient investigation over presence of ILs remaining on the surface of the catalyst and its participation in the photocatalytic reaction

# 6) Development of the surface

Improvement of the photocatalytic properties can be also realized through the development of the semiconductor surface. Higher specific surface area results in a larger number of reactive sites where photocatalytic reactions can occur. The increased specific surface area allows for more adsorption sites, enabling better adsorption of reactant molecules onto the photocatalyst's surface<sup>117</sup>. Higher surface area also improves the semiconductor's light-harvesting properties<sup>118</sup>. A larger surface area is available for light absorption, leading to increased utilization of incident photons and improved photoactivity. The increased surface area provides more pathways for charge carriers (such as electrons and holes) to migrate and participate in photocatalytic reactions. A more developed and oriented material's surface enables efficient charge transfer, reducing recombination and prolonging the lifetime of charge carriers<sup>119</sup>.

As shown in Table 6 by altering the IL composition it is possible to achieve semiconductors with high/higher specific surface areas, porosity, lower particle size, and specific morphologies. This has been achieved for various semiconductor materials such as TiO<sub>2</sub><sup>120</sup>, ZnO<sup>121</sup>, BiOI<sup>122</sup>, BiOBr<sup>123</sup>, BiOCI<sup>124</sup>, Bi<sub>2</sub>SiO<sub>5</sub><sup>125</sup>, BiPO<sub>4</sub><sup>126</sup>, SrSnO<sub>3</sub><sup>127</sup>, SnS<sub>2</sub>, <sup>128</sup> or composites  $such \ as \ TiO_2/CuO^{129}, \ Y_2O_3/TiO_2^{130}, \ Bi_2WO_6-Bi_2O_3^{131}, \ In_2S_3/TiO_2^{132}, \ MoS_2/Bi_5O_7I^{133}, \ MoS_2/Bi_5O_7I^{133},$  $BiOBr/BiOCl^{134}, \quad BiOCl/m-BiVO_4^{135}, \quad rGO\_Bi_2WO_6^{136}, \quad NH_2-UiO-66/BiOBr^{137}, \quad ZrO_2@_2 = 2000 + 1000 +$ HKUST-1<sup>138</sup>, Cu<sub>2</sub>S-MoS<sub>2</sub><sup>139</sup>, Ag<sub>3</sub>PO<sub>4</sub>/BiPO<sub>4</sub><sup>140</sup>. These materials were synthesized using various methods, including hydrothermal, solvothermal, microwave technique, microwaveassisted solvothermal synthesis, ultrasonic processing, and the sol-gel method. Among various ionic liquids, ethylammonium nitrate<sup>6141</sup>, 1-(2-methoxyethyl)-3-methylimidazolium 1-(triethoxysilylpropyl)-3-methylimidazolium methanesulfonate<sup>129,130</sup>, [CH<sub>2</sub>CH<sub>2</sub>]O<sub>2</sub>(mm)<sub>2</sub><sup>121</sup>, tetramethylammonium glycine<sup>143</sup>, glutamic acid tetrafluoroborate<sup>144</sup>, 1ethyl-3-methylimidazolium ethyl sulfate145, 1-methyl-3-[3'-(trimethoxysilyl)propyl]imidazolium<sup>146</sup>, 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>127,147</sup>, 1methyl-3-octylimidazolium bis(trifluoromethylsulfonyl)imide<sup>147</sup>, methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>147</sup>, 1-ethyl-2,3-dimethylimidazolium bis(trifluoromethylsulfonyl)imide147, trimethylbutylammonium bis(trifluoromethylsulfonyl)imide<sup>147</sup>, 1-butyl-3-methylimidazolium thiocyanate<sup>139,147</sup>, 1-butyl-2,3-dimethylimidazolium tetrafluoroborate<sup>148</sup>, 1-ethyl-3-methylimidazolium tetrafluoroborate<sup>148</sup>, 1-butyl-3-methylimidazolium hydroxide149, 1-dodecvl-3methylimidazolium hydroxide<sup>149</sup>, (2-hydroxyethyl)-trimethylammonium hydroxide<sup>149</sup>, 1-ethyl-3-methylimidazolium hexafluorophosphate<sup>150</sup>, 1-butyl-3-vinylimidazolium bromide<sup>123</sup>, poly-1butyl-3-vinylimidazolium bromide<sup>123</sup>, poly-1-butyl-3-vinylimidazolium bromide acrylamide<sup>123</sup>, 1-hexadecyl-3-methylimidazolium bromide<sup>151,152</sup>, choline chloride<sup>124</sup>, chlorinated pyridine<sup>124</sup>, imidazole chloride<sup>124</sup>, 1-methyl-3-octylimidazolium dihydrogen phosphate<sup>126</sup>, 1,6-bis(3methylimidazolium-1-yl)hexane bis(trifluoromethylsulfonyl)imide<sup>127</sup>, tetradecyltrihexylphosponium bis(trifluoromethylsulfonyl)imide<sup>127</sup>, 1-butylpyridinium bis(trifluoromethylsulfonyl)imide127, 1-hexyl-3-methylimidazolium chloride<sup>128</sup>, 1-butvl-3methylimidazolium acetate128, 1-allyl-3-methylimidazolium chloride<sup>131</sup>, 1-allvl-3-N,N,N,N',N',N'-hexakis(2-hydroxyethyl)ethane-1,2methylimidazolium bromide134, bromide138, diaminium 2-hydroxylethylammonium formate<sup>140</sup>, 1-hexadecyl-3methylimidazolium chloride<sup>153</sup>, 1-hexadecyl-3-methylimidazolium bromide<sup>137,153,154</sup>, 1-ethyl-3-1-butyl-3-methylimidazolium methylimidazolium iodide133, iodide122,155, 1-butyl-3methylimidazolium bromide<sup>2,128,156</sup>, 1-butyl-3-methylimidazolium chloride<sup>2,128,131,132,135,157</sup>, 1-butyl2,3-dimethylimidazolium chloride<sup>132</sup>, 1-butylpyridinium bromide<sup>158</sup>, 1-methyl-3-octylimidazolium tetrafluoroborate<sup>3</sup>, and 1-butyl-3-methylimidazolium tetrafluoroborate<sup>58,110,120,125,128,136,148,159</sup> have been widely employed in the semiconductors' synthesis, as shown in Table 6. The aforementioned ILs were added during the synthesis process, serving multiple roles including solvent<sup>122</sup>, surface/morphology directing agent<sup>125,127</sup>, reactant<sup>123</sup>, template<sup>160</sup>, source of phosphate<sup>126</sup>, iodine<sup>133</sup>, fluorine<sup>159</sup> and chlorine <sup>124</sup>, as well as functioning as an additive<sup>2</sup> and stabilizer<sup>160</sup>.

As summarized in Table 6, the enhanced photocatalytic activity was attributed to several factors: reduced particle size, increased BET surface area, decreased particle aggregation, and the formation of uniform morphologies such as spheres. Additionally, better porous microsphere structure, larger pore volume and size played a significant role. Beyond these factors, the most commonly observed phenomena contributing to increased photocatalytic activity included lower electron-hole recombination, suitable energy band structure, narrower band gap structure, presence of oxygen vacancies, and degree of crystallinity. Paszkiewicz et al.<sup>2</sup> reported that the inclusion of 1-butyl-3-methylimidazolium chloride and 1-decyl-3methylimidazolium chloride in the solvothermal synthesis of TiO2 led to improved photoactivity. This enhancement was due to a reduction in particle size, an increase in surface area, and a more regular shape of microspheres compared to the unmodified sample. On the other hand, by altering the types of ILs in terms of both anions and cations, ZnO materials with varying morphologies could be synthesized, specifically nanospheres of different diameters and nanorods with varying lengths and diameters 160. The morphology of the nanospheres was crucially influenced by the use of 1-methyl-3-octylimidazolium bis(trifluoromethylsulfonyl)imide 1-decyl-3-methylimidazolium or bis(trifluoromethylsulfonyl)imide, obtained using 1-butyl-3while nanorods were methylimidazolium bis(trifluoromethylsulfonyl)imide, 1-ethyl-2,3-dimethylimidazolium bis(trifluoromethylsulfonyl)imide, trimethylbutylammonium bis(trifluoromethylsulfonyl)imide, and 1-butyl-3-methylimidazolium thiocyanate<sup>160</sup>.

Development of the surface can be measured by gas adsorption techniques, atomic force microscopy (AFM), scanning electron microscopy (SEM), and TEM mercury porosimeter<sup>124,137,140,156,161,162</sup>. Alammar and Mudring<sup>160</sup> synthesized ZnO using five different ILs exhibiting various morphology including nanorods, nanospheres, prismatic, flower-like, and nanosheets and morphological parameters such as shape, diameter, and length were possible to determine based on SEM and TEM imaging. Based on nitrogen adsorption–desorption isotherm measurements it was possible to determine BET surface areas of the prepared samples. It was found that the highest surface area reaching the value of 55 m²/g was achieved by synthesizing ZnO nanospheres with a diameter of 100 nm using IL 1-decyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>160</sup>.

As shown in Table 6, the enhancement of photocatalytic properties via the application of ionic liquids to the development of the semiconductor's surface has been the subject of extensive and intensive research in recent years. While the existing research has shed light on the benefits of using ionic liquids in enhancing photocatalytic activity, there remains a critical need for a deeper and more precise understanding of the key factors driving this enhancement. The current hypotheses, which suggest improvements due to unique morphology, reduced particle size, or minimized aggregation, lack clear and consistent support. It is essential to establish more concrete evidence to validate these theories and to identify the principal

mechanisms responsible for the observed enhancements in photocatalytic activity. Although the majority of photoactivity studies have predominantly focused on the degradation of pollutants, it is recommended to broaden the scope of research to encompass other significant reactions. These include hydrogen photogeneration, CO<sub>2</sub> photoreduction, and the transformation of organic compounds. There is currently a lack of clarity regarding the presence of ionic liquids or their residues on semiconductor surfaces and how this might impact subsequent processes, such as photocatalytic reactions.

*Known:* effect of a wide range of ILs on semiconductor morphology, increased activity in photodegradation of pollutants, ILs decomposition during synthesis of semiconductors, growth mechanisms.

*Unknown:* what role do the remaining ionic liquids or their residues present on the semiconductor play? which parameter plays a key role in enhanced oh photoactivity, and other photocatalytic applications such as CO<sub>2</sub> photoconversion.

Table 6. Category: development of the surface. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*,\*\*.

- surface properties: diameter  $(\varphi)$ , thickness (th), length (l), width (w), crystallite size (D) specific surface area  $(S_{BET})$ , pore volume  $(V_p)$ , pore size  $(\varphi_p)$ , aspect ratio,
- conditions: photocatalyst content (Cphot), the concentration of model pollutant (C0), sacrificial agent (sacr. agent), volume of solution (Vs), irradiation time (t),
- efficiency: yield (Y)/rate (r)/rate constant (k) of the most active sample (Y), and the reference sample ( $Y_{ref}$ ),  $\nearrow$  increase, and  $\searrow$  decrease compared to the reference sample.

<sup>\*\*</sup>The original sample label is given in italics.

Photocatalyst					Photocatal	ytic performance			
and original sample label	Ionic liquid and its role in the synthesis	Synthesis method	Surface properties	Type of model reaction	Conditions	Light source	Yield (Y)/rate (r)/rate constant (k)	Mechanism details	Ref.

## 7) Surface modification

In photocatalytic reactions, various subsequent processes occur at the interface between the semiconductor and the components of the reaction medium. These steps typically involve the initial adsorption of reactants, followed by the reaction itself, and finally the desorption process<sup>17</sup>. Therefore, improvement of photocatalytic properties can occur by enhancing the adsorption of specific molecules on a semiconductor surface<sup>163,164</sup>. This increased adsorption promotes a higher concentration of reactants at the surface, facilitating more efficient photocatalytic reactions. One way to influence the adsorption of reactants is to modify the semiconductor surface with ionic liquids. ILs or IL-derived residues formed during synthesis can alter the surface charge, polarity, and enter functional groups, affecting the adsorption behavior of reactant molecules on a semiconductor surface.

Table 7 provides an overview of the enhancement of photocatalytic activity through surface modification of semiconductors using ionic liquids. These modifications can indeed be carried out during the synthesis of the semiconductor material or as a post-synthesis modification<sup>166</sup>. In some cases, an ionic liquid was added directly to the semiconductor during the investigation of photocatalytic activity<sup>167</sup>. Surface modification using ILs was carried out on various semiconductor materials, including TiO2167, C3N4 168, as well as the bismuth-based compounds BiOBr/Bi<sub>2</sub>WO<sub>6</sub><sup>169</sup> and BiOI <sup>165</sup>. In most cases, ionic liquids (ILs) were applied to the surface of semiconductors using the impregnation method. To achieve surface modification aimed at enhancing photoactivity the following ILs have been employe 1-butyl-3-methylimidazolium imidazolate, 1-butyl-1-metylpyrrolidinium imidazolate, tributylethylphosphonium imidazolate [(But)<sub>3</sub>EP][Im], [P<sub>4444</sub>]<sub>3</sub>[p-2,6-O-4-COO], [P<sub>4444</sub>]<sub>2</sub>[p-2-[P4444][p-4-COO]<sup>170</sup>,  $[P_{4444}][p-2-O],$ 1-butyl-3-methylimidazolium tetrafluoroborate<sup>167</sup>, 1-butyl-3-methylimidazolium iodide<sup>165</sup>, 1-butylpyridinium bromide<sup>169</sup>, 1chloride<sup>166</sup>, 1-butyl-3-methylimidazolium butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide<sup>166</sup>, 1-ethyl-3-methylimidazolium tetrafluoroborate<sup>168</sup>.

The presence of the 1-butyl-3-methylimidazolium cation was found to promote the adsorption of methyl orange molecules onto the TiO<sub>2</sub> surface<sup>167</sup>. Suppression of recombination in photoinduced electron-hole pairs in BiOI was possible to achieve by effectively capturing and trapping the photogenerated electrons through the surface modification provided by 1-butyl-3methylimidazolium iodide<sup>165</sup>. The N- and Br-modified surface of BiOBr/Bi<sub>2</sub>WO<sub>6</sub> originated from the application of 1-butylpyridinium bromide enhanced photocatalytic activity in the degradation of phenol under visible light<sup>169</sup>. Liu et al.<sup>168</sup> discovered that the incorporation of 1-ethyl-3-methylimidazolium tetrafluoroborate into the Co-B-C<sub>3</sub>N<sub>4</sub> surface resulted in enhanced efficiency in the conversion of CO<sub>2</sub> into CH<sub>4</sub> and CO through photocatalysis. This improvement was attributed to the surface loading of IL, which acted as a cocatalyst, facilitating the achievement of superior photocatalytic performance. Additionally, the impregnation of TiO<sub>2</sub> with IL led to modifications in the surface electronic structure. It was observed that TiO<sub>2</sub>-bearing imidazolate anions from the IL reduced the activation energy barrier for the CO<sub>2</sub> photoreduction reaction <sup>166</sup>. On the other hand, Łuczak et al. <sup>12</sup> found out that ILs or organic residues derived from ILs can create a unique form of surface modification that enhances photocatalytic activity in the phenol degradation reaction. This surface modification of TiO<sub>2</sub> involves covering the surface with an amorphous layer consisting of either hydrophobic organic residues or hydrophilic, likely ionic, organic residues.

Surface modifications of semiconductors using ILs can be identified using a wide range of techniques, such as: XPS<sup>12</sup>, FTIR<sup>171,172</sup>, DRS UV-Vis,<sup>99</sup> and electrophoretic mobility<sup>173</sup> measurements. For example, the IR spectrum of IL-modified BiOI and 1-butyl-3-methylimidazolium iodide exhibited distinct peaks at 1170, 815, and 714 cm<sup>-1</sup>, which were absent in the spectrum of the reference sample (P-BiOI)<sup>165</sup>. These peaks, indicative of plane deformation and out-of-plane deformation of the C-H bond suggested successful surface modification of BiOI by ILs. The confirmation of IL surface impregnation can be achieved by analyzing the C1s spectrum, particularly through the detection of components attributed to the C=C aromatic carbon bond. Additionally, the presence of IL species on the surface can also be confirmed by examining the N1s and Br 3d spectra<sup>169</sup>.

The field of semiconductor surface modification with ILs has shown promising results, particularly in photocatalytic applications. However, to fully harness this potential, several key areas require further exploration and improvement. Current research primarily utilizes a limited range of ionic liquids. The development of methods enabling the adsorption of ionic liquids during semiconductor synthesis must ensure that the ionic liquids are effectively integrated without undergoing degradation or decomposition. A deeper understanding of the photocatalytic reactions in the presence of ionic liquids is essential. This can be achieved by corroborating experimental findings with theoretical studies. Such an approach would provide a more comprehensive understanding of how these reactions occur and the role ionic liquids play in them. Determining the universal role of ionic liquids, based on their type, in photocatalytic reactions would be a significant advancement.

*Known:* the creation of junctions between semiconductors and ILs, increases photoactivity by lowering energy activation,

*Unknown:* more specific role of ILs depending on ILs structure, stability of ILs during measurements, effect on mass and charge carrier transfer as well as selectivity of reaction.

Table 7. Category: surface modification. Preparation conditions, morphology, photocatalytic performance of photocatalysts prepared by ILs-assisted synthesis methods\*,\*\*.

- surface properties: diameter ( $\varphi$ ), thickness (th), length (1), width (w), crystallite size (D) specific surface area ( $S_{BET}$ ), pore volume ( $V_p$ ), pore size ( $\varphi_p$ ), aspect ratio,
- conditions: photocatalyst content (Cphot), the concentration of model pollutant (C0), sacrificial agent (sacr. agent), volume of solution (Vs), irradiation time (t),
- efficiency: yield (Y)/rate (r)/rate constant (k) of the most active sample (Y), and the reference sample (Y<sub>ref</sub>),  $\nearrow$  increase, and  $\searrow$  decrease compared to the reference sample.

## 8) Thickness control

Ultrathin two-dimensional (2D) materials composed of single, or few layers have garnered significant interest owing to their fascinating physical-chemical properties. As photocatalytic materials decrease in thickness, they exhibit novel properties that are not present in analogous three-dimensional (3D) counterparts 174,175. 2D materials typically have a higher surface area that provides more active sites for catalytic reactions. This increased surface area is attributed to the unique geometry of 2D materials (having length and width, but negligible thickness). Among their advantages can be mentioned: (i) more exposed active sites (atoms or functional groups on the surface of 2D materials are more exposed and accessible, making them more reactive), and (ii) more efficient adsorption of reactant molecules onto the material's surface. Besides, 2D materials possess shorter diffusion paths resulting in faster charge carrier transport, reducing the likelihood of recombination and enhancing the overall efficiency of the photocatalytic process<sup>176,177</sup>. They can exhibit enhanced light absorption due to the quantum confinement effect and reduced light reflection<sup>178,179</sup>. Controlling the thickness allows for tuning the band alignment, ensuring that the energy levels of the valence and conduction bands are suitable for promoting charge separation and facilitating redox reactions. Evaluation of material thickness can be conducted using SEM<sup>180–185</sup>, TEM <sup>180–187</sup>, AFM <sup>180,182</sup>, and highangle annular dark-field scanning transmission electron microscopy (HAADF-STEM)<sup>188</sup>. These techniques insights into the morphological characteristics and thickness uniformity of the synthesized materials.

The application of specific ILs, as illustrated in Table 8, such as 1-hexyl-3-methylimidazolium iodide<sup>184,185</sup>, 1- hexadecyl-3-methylimidazolium bromide<sup>180–182,187,189</sup>, 1-butyl-3-methylimidazolium iodide<sup>186</sup>, and tetrabutylammonium chloride<sup>183</sup>, played the crucial role in the precise regulation of the thickness of ultrathin 2D materials. Imidazolium-based ILs are commonly employed in the synthesis of 2D ultrathin nanosheets due to their unique properties. The formation of hydrogen bonds between the hydrogen atom in ILs' aromatic ring and the oxygen atoms from the external plane of photocatalysts facilitates the uniform adsorption of nuclei at the initiation of the reaction. By adjusting the amount of IL, control over the number of adsorbed hydrogen bonds on the crystal surface is achieved, leading to preferential growth along the 2D direction<sup>190</sup>.

The literature data demonstrate that ILs have a significant impact on the morphology to form thinner nanosheet structures. It is known that ILs can work in two ways (i) provide halogen atoms to form photocatalyst 2D nanostructures 182,184,185, and (ii) as morphology-directing agents facilitating the formation of ultrathin materials in the range of 3 – 8 nm 182,183. In addition, the presence of ILs could potentially influence the growth and stability of the nanosheets during the synthesis 180. It can be inferred that these ultrathin nanosheets have a notably brief distance for the diffusion of photoinduced carriers. This characteristic proves advantageous in effectively separating and transferring photoinduced carriers from the bulk phase to the surface of the photocatalyst, thus contributing to improved photocatalytic performance 185,187. In the case of heterojunction, IL as a source of halogen atoms can form a bridge to facilitate the intimate integration of two different components and play a crucial role in the formation and stabilization of heterojunctions 181. In addition, the uniform dispersion of ultrasmall nanosheets on the ultrathin photocatalyst surface ensures a well-distributed and intimate contact between the 2D-2D materials 184.

While the use of ionic liquids (ILs) in the synthesis of 2D photocatalysts can offer several advantages, it's essential to consider potential challenges or "white spots" that may arise. The presence of residual ILs can alter the material properties and affect photocatalytic performance. It's crucial to develop effective methods for IL removal to ensure the purity of

the final product. Currently, little is said about the methods of how to remove them. To optimize IL-assisted synthesis, researchers need to delve deeper into the mechanisms through which ILs interact with precursor materials, affect growth processes, and influence the resulting morphology and properties of 2D photocatalysts. Understanding how ILs influence the band structure, energy levels, and charge carrier dynamics is crucial for tailoring these materials for specific photocatalytic applications.

*Known*: facilitate formation of ultrathin materials (morphology-directing agent); provide halogen atoms to form 2D materials, bridge heterojunctions, and ensure uniform dispersion of ultrasmall nanosheets on the photocatalyst surface in 2D-2D materials;

*Unknown*: mechanisms of IL or its residual interaction with precursor of 2D materials;

## **Conclusions and future prospect**

Increasing the maturity of technology using heterogeneous photocatalysis requires rational design and synthesis of new photocatalytic materials and application of reagents affecting the final properties of obtained materials, such as ionic liquids-assisted materials. Thus, this paper distinguishes and summarizes eight main mechanisms describing interactions between ionic liquids and growing semiconducting particles and their final effect on surface and photocatalytic properties of semiconductors, i.e.: (i) doping of elemental atoms from ILs, (ii) surface defect formation, (iii) formation of charge transfer surface complex, (iv) promoting of charge transfer; (v) facet-control synthesis; (vi) altering size and porosity of materials, (vii) affecting sorption properties due to presence of ILs, and (viii) regulating the thickness of synthesized materials.

The choice of ionic liquids for the synthesis of semiconductor particles should be preceded by a theoretical consideration of how this ionic liquid will behave during synthesis, including whether it will not decompose during solvothermal synthesis. Very generally it can be stated that ionic liquids that are not stable under elevated temperature and pressure conditions could be used as a source of elements doped into the crystal structure of semiconductor particles and finally affect their band structure. On the other hand, ionic liquids surviving conditions of solvothermal synthesis could be adsorbed at the surface of the semiconductor and form a charge-transfer complex between an electron acceptor (semiconductor) and an electron donor (surface adsorbate). This kind of interaction (i.e. the presence of CT-complex) could shift the photoactivity of semiconducting materials from the UV region to visible light.

The wide spectrum of imidazolium ionic liquids have been used to promote the intentional formation of oxygen vacancies especially in the case of TiO<sub>2</sub> or to form surface defects in the case of other materials such as ZnO, BiOBr, or BiVO<sub>4</sub>. The existence of surface defects could suppress the recombination of photoinduced electron-hole pairs, which is crucial for the photoactivity of excited semiconductor material. Moreover, surface defects may appear to narrow the band gap (by creating new energy states in the band gag) and work as active sites, affecting finally observing reaction efficiency.

Finally, ionic liquids could serve as additives helpful in morphology control by influencing the type of facets/planes formed during synthesis, the thickness of the resulting nano- and microparticles, as well as their size and porosity.

Therefore, careful analysis of the ionic liquid's properties and their appropriate selection for the synthesis of semiconductor materials is a promising way of synthesizing materials with the desired photoactivity but requires further systematic research. It seems particularly desirable to use theoretical methods that allow predicting these interactions between the ionic liquid and the growing semiconductor particles, such as Virtual High Throughput Screening, including predictive multi-scale Molecular Modeling and Machine Learning based models.

Moreover, based on available literature we have diagnosed the following challenges for the future in this field:

- 1. The use of ionic liquids for the synthesis of semiconductor photocatalysts as a reagent that allows controlling the selectivity of obtained materials (e.g. obtaining photocatalysts possessing the assumed selectivity in the CO<sub>2</sub> photoreduction or alcohol oxidation reactions);
- 2. The employment of ionic liquids for the synthesis of semiconductor photocatalysts as a reagent allows obtaining photocatalysts activated by sunlight. Even if there are now reports of obtaining photocatalysts activated by light in the visible range, no studies

- are showing whether such photocatalysts are useful for use on a larger scale and in the presence of solar radiation;
- 3. There is a lack of research showing whether photocatalysts obtained in the presence of ionic liquids are characterized by long-term stability, because the ionic liquid or its decay products being on the surface of the photocatalyst may undergo transformations in photocatalytic processes and thus affect its activity. This aspect would also require deeper research;
- 4. To understand the role of ionic liquids in the interaction with the semiconductor particle during its growth and in its use in the photocatalytic reaction there is a need to have easily accessible data on the type of interactions and their strength between ionic liquids and their degradation products and the surface of semiconductors.

#### **Author contributions**

J. Ł. wrote the Sections 1 and 4. A. P. wrote the Sections 2 and 8. M. K. wrote the Sections 3 and 5. P. M. wrote the Sections 6 and 7. A. Z. M. wrote the Introduction and Conclusions parts. P. M. prepared the figure. A. P. and M. K. combined, formatted, and proofread the manuscript. J. Ł. and A. Z. M. led and coordinated the writing of this paper. All authors provided critical feedback and helped shape the manuscript.

### **Conflicts of Interest**

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

## Acknowledgements

This research was supported by the Polish National Science Center under the grant 2021/41/B/ST4/00849.
